Foreword

This report summarizes the results of a three-year investigation of the geology and geochemistry of Grenville marble in Southeastern Ontario.

This material is a source of building stone, crushed stone, terrazzo chips, poultry grit, lime, and magnesium metal. A recent increase in the demand for calcium carbonate with qualities of high brightness (whiteness) and purity has led to renewed exploration activity. This high-quality material has the potential for use as a filler in products such as paints, plastics, floor tile, paper finish, and glass.

The purpose of the investigative survey was threefold: a) to identify areas of high-purity marble suitable as an industrial mineral source; b) to assess the variability, both geochemically and geologically, of marble; and c) to determine regional calcium/magnesium trends within individual marble belts as a guide to industrial mineral and base-metal mineralization. To meet the urgent demand for the identification of marbles of high purity in the study area, emphasis was placed upon the rapid chemical analysis of a large sample population. As a follow-up, areas containing high-purity marbles, as indicated by regional samples, were mapped in detail to better define the extent of the high-purity marble.

Exactly 1912 samples were collected from lithologically homogeneous marble units, and these samples were chemically analyzed for up to 28 elements, plus Loss on Ignition, under the direction of the Geoscience Laboratories of the Ontario Geological Survey. Examination of the chemical data for the 1912 samples allowed the selection of 58 sites where CaO exceeds 54 weight percent and SiO_2 plus Al_2O_3 is less than 1 weight percent in marble; and an additional 12 sites where the ratio of CaO to MgO is on the order of 1.4 and SiO_2 plus Al_2O_3 is less than 1.5 weight percent in marble. Rocks of these compositions are chemically suitable for the filler, lime, and whiting industries, and are low in abrasiveness, a requirement for use as filler material. The 70 sites were mapped in detail to assess the possible tonnage potential, geological continuity, and chemical consistency over a wide area.

This investigation has been partly funded by the Ministry of Natural Resources and the Canada Department of Regional Economic Expansion under the Canada–Ontario Eastern Ontario Subsidiary Agreement.

Manuscript approved for publication by C.R. Kustra, Regional Liason Geologist, June 1984. Report published with the permission of V.G. Milne, Director, Ontario Geological Survey.

Abstract

The history of industrial mineral exploration and production in Southeastern Ontario indicates a widespread occurrence of potentially exploitable Grenville marble. This marble makes up a large portion of the Central Metasedimentary Belt, of Precambrian age. This belt is a small part of the Grenville Province which trends northeast through Ontario, Quebec, and Labrador.

In order to aid industry in the exploration for high-quality calcium carbonate and calcium carbonate-hosted deposits, a regional sampling survey was conducted over much of Southeastern Ontario. Exactly 58 areas with greater than 54 weight percent CaO and less than 1 weight percent combined SiO_2 plus Al_2O_3, and 12 areas with a ratio of CaO to MgO of approximately 1.4 and less than 1.5 weight percent combined SiO_2 plus Al_2O_3 in marble were identified and mapped in detail. The marble was examined for its potential as industrial filler material, aggregate material, and building stone.

Quantitative statistical analysis of the chemical data was undertaken by computer to examine the elemental relationships of the different marble types, with the aim of identifying and characterizing carbonate-hosted deposits.

Résumé

L'historique de l'exploration et de la production minéralogique industrielle dans le Sud-Est de l'Ontario révèle la présence de nombreux gisements de marbre de Grenville exploitables. Ce type de marbre est un des principaux éléments qui composent la zone centrale de roche sédimentaire précambrienne métamorphisée. Cette zone ne représente qu'une partie de la province de Grenville qui traverse, en direction nord-est, l'Ontario, le Québec et le Labrador.

Afin d'aider l'industrie à découvrir des gisements de carbonate de calcium et des dépôts contenant du carbonate de calcium de qualité, une étude d'échantillonnage régionale a été effectuée sur la plupart du territoire du Sud-Est de l'Ontario. Cinquante-huit régions dont le marbre contenait plus de 54 pour 100 par poids de CaO et moins d'un pour cent par poids d'un combiné de SiO_2 et de Al_2O_3, et douze régions dont le marbre avait un rapport CaO–MgO d'environ 1,4 et qui contenait moins de 1,5 pour 100 par poids d'un combiné de SiO_2 et de Al_2O_3 ont été identifiées et cartographiées en détail. On a étudié les utilisations possibles du marbre comme matériau industriel de remblai, matériau d'agrégat et pierre de construction.

On a effectué au moyen d'un ordinateur une analyse statistique quantitative des données chimiques afin d'étudier la relation élémentaire des différents types de marbre en vue d'identifier et de caractériser les dépôts contenant du carbonate.

Geochemistry of Grenville marble in southeastern Ontario, by W.T. Grant, V.C. Papertzian, and P.W. Kingston. Ontario Geological Survey, Mineral Deposits Circular 28, 266p. Published 1989. ISBN 0-7729-5444-5.

Introduction

Throughout the history of industrial mineral exploration in Southeastern Ontario, marble has been a much sought-after commodity. Traditional uses of this material have been building stone, crushed stone, terrazzo chips, poultry grit, lime, and as a source of magnesium metal, to name a few. A recent increase in the demand for calcium carbonate material with qualities of high brightness (whiteness) and purity has led to renewed exploration activity. This high-quality material has the potential for use as a filler in paints, plastics, floor tile, paper finish, glass, and many other finished products of more limited quantity.

Marble belts throughout the study area occur at different levels within the Grenville stratigraphic column, alternating with different rock types of sedimentary, volcanic, and intrusive origin. Characteristics of each calcium carbonate rock type are determined by its history of development. Compositional and textural differences between marble types reflect differences in the original depositional environments, as well as differences in the metamorphic grade or type of metamorphism.

Marble is important, not only as a source rock for industrial minerals, but also as a host rock for secondary industrial minerals (for example, talc), base metals, uranium–thorium, and other types of deposits (Storey and Vos 1981). The calcium carbonate sampling survey undertaken in this study is similar to that of Storey and Vos (1981), covering a different but adjacent geographical area (Figure 1). To allow an easy comparison between the marble

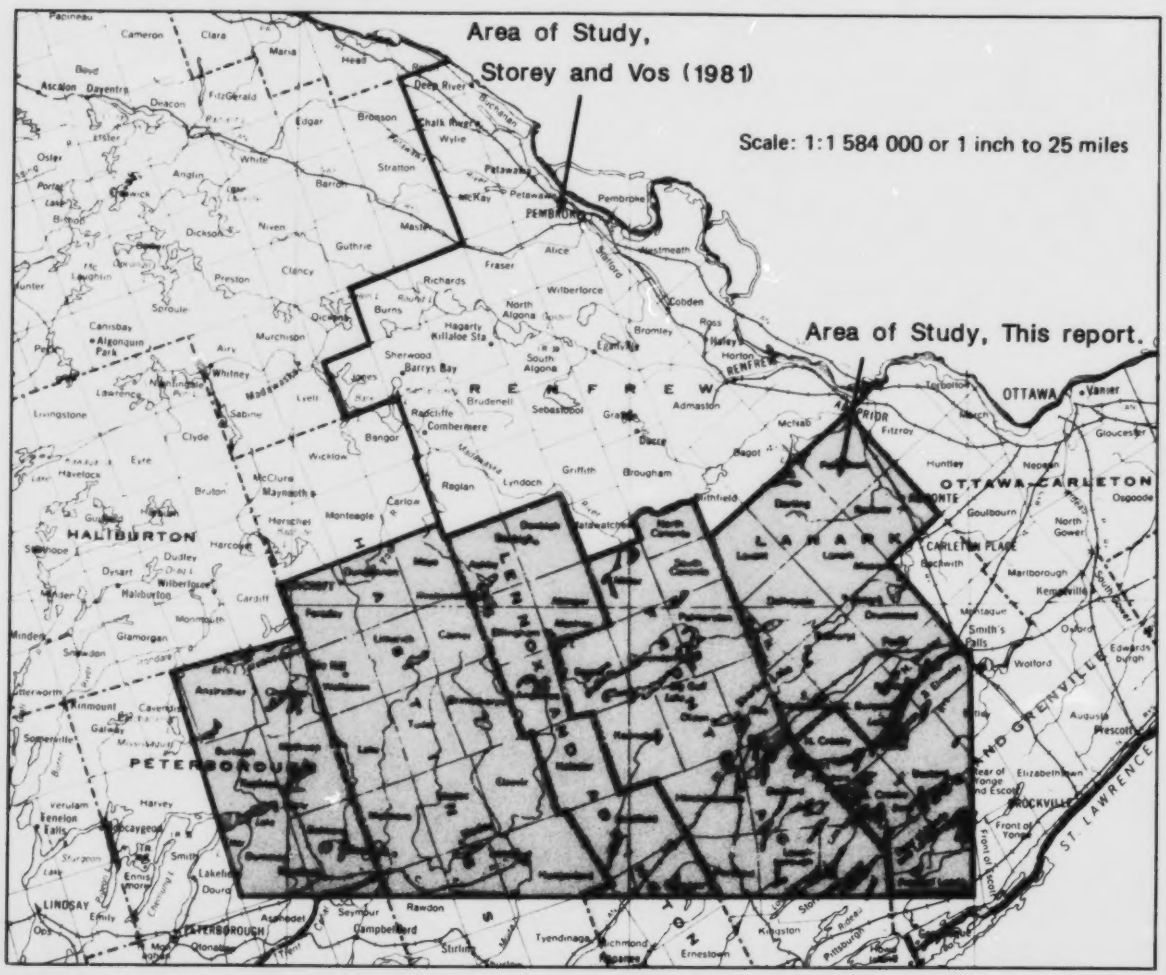

Figure 1. *Location map of the study area indicating the area of the calcium carbonate survey, as well as that of a previous calcium carbonate survey (Storey and Vos 1981).*

units discussed in the separate publications, this publication will follow the basic outline used by Storey and Vos (1981).

This publication includes a compilation (Appendix A) of the chemical data of 1912 samples collected over a period of four summers. This data has been previously published (Papertzian and Kingston 1982a, 1982b; Grant and Kingston 1984). From the complete sample group of 1912 samples, 58 sample locations indicating high-calcium (calcitic) marble and 12 sample locations with high-magnesium (dolomitic) marble samples—all of which were considered, from geochemistry, to have high development potential—were mapped in detail. These sample location maps are included within this publication.

The chemical data of all 1912 samples were examined by statistical analysis using histograms, correlation matrices, and X–Y plots. Original copies of the computer analysis may be examined at the Resident Geologist's Office, Southeastern District, Tweed.

Acknowledgments

The authors wish to thank the many landowners who allowed access to their respective properties. Field assistance was provided by Gordon Keep, Paul Barbour, and Rob Palkovits. Maps were drafted by Al Fulton and Leila Thatcher. Special thanks are directed to O.P. Lavin for his assistance in the computer analysis of the carbonate data. Discussions with Janet Springer of the Ontario Geological Survey were helpful in many portions of this project. M.A. Klugman deserves credit for initiating the project.

Regional Geology

The study area is located within the Central Metasedimentary Belt (as defined by Wynne-Edwards 1962), which comprises rocks belonging to the Grenville Supergroup. The Central Metasedimentary Belt consists of metasedimentary, metavolcanic, and metaigneous rocks of Precambrian age. The regional metamorphic grade ranges from greenschist facies east of Madoc, to granulite facies in the Kingston–Gananoque area (Hewitt 1964a). The distribution of metamorphic grade is illustrated in Figure 2.

The Grenville Orogeny, at approximately 1000 Ma, imposed an overall northeastern structural trend over most of the Central Metasedimentary Belt (Stearn *et al.* 1979). The majority of the marble belts examined during this study show this northeastern structural trend (Figure 3), although some are also affected by more local structural events.

The Precambrian rocks of the Central Metasedimentary Belt are overlain in Southeastern Ontario by flat-lying Paleozoic sedimentary and carbonate rocks. The contact between the Precambrian and Paleozoic sedimentary rocks is unconformable, with a time gap of approximately 600 Ma (Holmes 1960).

SAMPLING AND MAPPING TECHNIQUES

In order to recognize the full potential of the sample analysis, a review of the methods used in regional sampling and in the mapping of specific sample areas is given below. A total of 1912 sets of data, equal to the number of samples collected and analyzed, was available for examination.

The total data set consists of two parts: Part 1, which includes geochemical data for 1778 samples (Papertzian and Kingston 1982a, 1982b); and Part 2, which includes geochemical data for 132 samples (Grant and Kingston 1984).

Most samples were taken from roadside outcrops or from quarries, with the exception of 50 samples which are identified by sample numbers ending in v, w, x, y, or z (Appendix A, Part 2). These are channel samples taken from outcrop surfaces in detailed map areas and were sampled to evaluate overall chemical consistency for a given area. Because it was not possible to clean the surfaces of these outcrops thoroughly, there may have been minor contamination.

The object of regional sampling was to sample the average material for each outcrop. However, above average marbles, in terms of whiteness and lack of impurities, have been commonly sampled.

Each detailed map included in this publication covers a limited area around the actual sample locations. These maps are intended to show the areal extent of the marble around the sample locations only, and do not give a detailed geological profile of each map area. The industrial minerals industry is primarily interested in the distinction between high-calcium marble and any other rock type closely associated with that marble, the latter of which to the industry is simply a contaminant that might make a deposit uneconomic. For this study, therefore, all rock types other than marbles were grouped using simplified field terms, which appear throughout the text and in the figures. Since sampling was restricted to roadside outcrops and quarries, better sampling areas may have been overlooked.

The marbles are generally grouped into calcitic and dolomitic marble types for the purpose of geological mapping. For convenience in the field, a simple acid test was used to distinguish between the two types. Outcrop descriptions that refer to impurities within the marble are based on visual examination in the field, representing average material in an outcrop.

MARBLE UNITS

Marble belts within the study area are variable in size, shape, and in both chemical and mineralogical composition. The size of the belts ranges from a few metres to several kilometres in width, and from a few hundred metres to tens of kilometres in length. Structurally, the belts differ according to the local geology and bounding structures, but most show a northeastern trend. Texturally, the marbles exhibit a wide variability, both between marble belts and within a single belt. The most dramatic examples of textural differences exist between low-grade regionally metamorphosed metasediment-hosted marble, and marble that has locally undergone contact metamorphism by the intrusion of igneous rocks.

Marbles associated with metasediments and metavolcanics are usually fine grained, grey in colour, and have fine dark and light grey laminations (Photo 1). These laminations and/or foliations are well defined and are often paralleled by elongate siliceous or dolomitic clots. Laminations are found in marbles that have been affected by low-grade metamorphism, and presumably reflect the original bedding of the carbonate unit. The laminated appearance is a result of alternating bands of variable grain size and impurity (predominantly graphite) content.

Marble that has been intruded by igneous bodies is normally coarse grained, and varies from white with shades of blue, to green, orange, or grey. This marble is characterized by an absence of planar structures, with the exception of flow foliation. Impurities such as graphite and phlogopite generally oc-

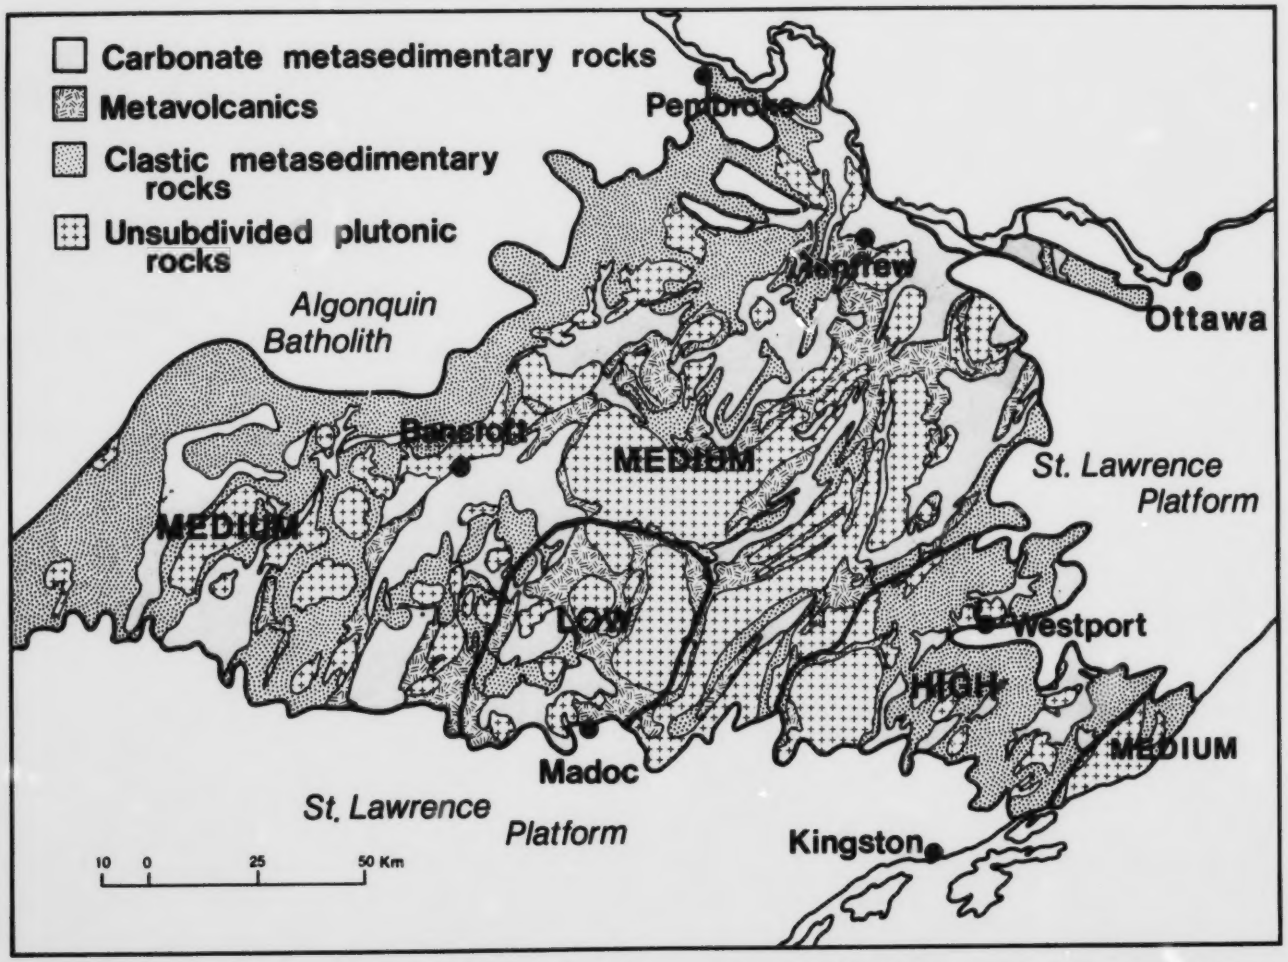

Figure 2. *Distribution of metamorphic grade in the Central Metasedimentary Belt, Grenville Province, Ontario (from Carter 1984).*

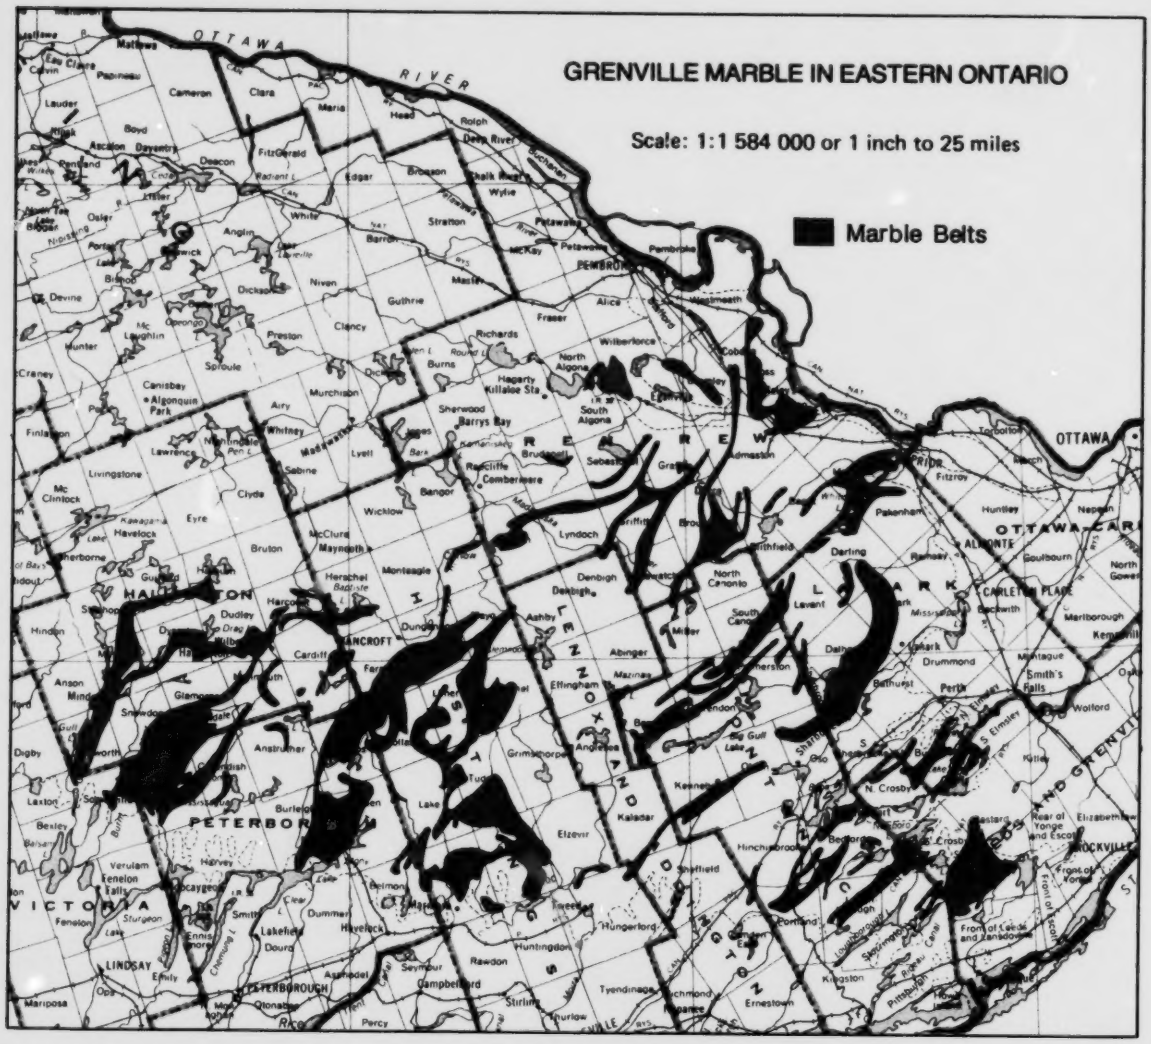

Figure 3. *Distribution of the major marble belts in the Central Metasedimentary Belt, Grenville Province, Ontario (Hewitt 1964c).*

cur along grain boundaries within the coarsely recrystallized material.

In many areas, such as around the Charleston Lake area (approximately 40 km south of Perth), it is apparent that it is the grade and not the type of metamorphism that is the major influence on marble texture. Where high-grade regional metamorphism is prevalent, marble is generally coarsely recrystallized into idioblastic grains.

There is a widespread occurrence of large silicate segregations and clots (5 to 50 cm in length) within the marble units (Photo 2). The grain size of the segregations is the same as that of the marble, and grains are often idioblastic. These segregations commonly occur far from any possible external source, and therefore are likely the result of the remobilization of silica within the calcium carbonate material during metamorphism. Two other suggestions as to the origin of these silicate segregations are: a) these clots were derived from a pegmatite (Wynne-Edwards 1962) or other similar intrusion; and b) these clots are relict sedimentary beds deformed during metamorphism (Harding 1951; Lumbers 1969).

Igneous intrusive rocks that are in contact with calcium carbonate rocks in the high-grade metamorphic regions are typically white and have a larger grain size than less altered equivalents. The whiteness of the intrusive rocks is likely due to the bleaching of feldspar by the migration of solutions from the carbonate material. Bleaching occurs as a result of the reduction of Fe^{+3} to Fe^{+2} in feldspar by fluids migrating near the intrusive contact (Wynne-Edwards 1962). It became evident during this study

Photo 1. *Grey laminated and contorted marble.*

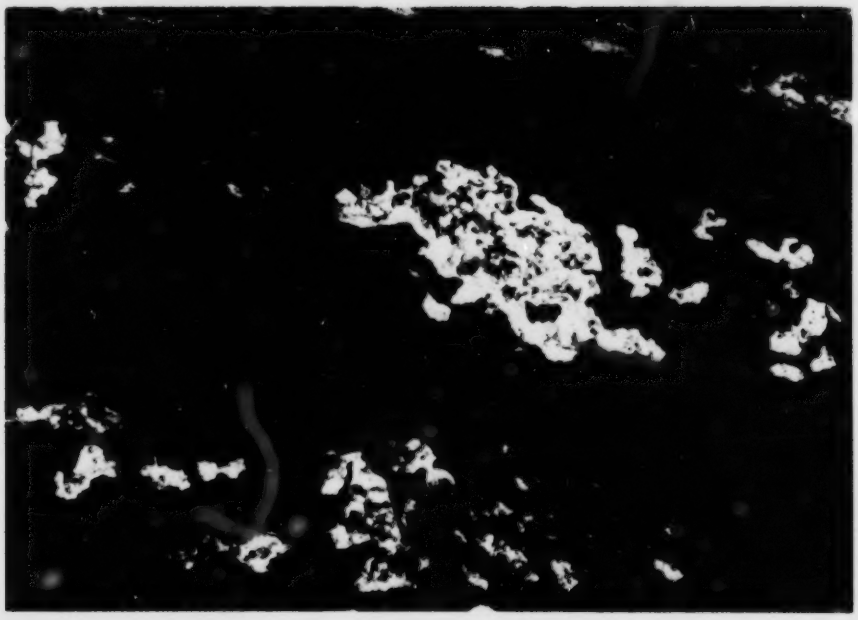

Photo 2. *Calc-silicate clots in dolomitic marble.*

that igneous intrusions into marble do not greatly alter the chemistry of the marble even near the contact where an alteration halo might be expected. Contacts are generally sharp and marble xenoliths within igneous host rocks do not seem to be altered chemically.

The frequent occurrence of dolomitic marble adjacent to metavolcanic units suggests that a relationship exists between these two rock types (Lumbers 1969). Dolomitic marbles associated with metavolcanics generally contain an abundance of silica or silicate stringers parallel to, and less com-

monly crosscutting, the foliation. It is unclear whether these stringers are due to the remobilization of silicate material within the marble, or if they are derived from fluids generated within the volcanic rocks during metamorphism and subsequently injected into the marble.

FIELD METHODS

Regional field sampling of marble with accompanying outcrop descriptions was begun in 1980. The majority of marble belts in the area are crosscut by roads, making it possible to obtain a section across most belts by roadside sampling. Care was taken to sample fresh outcrop where possible on an 800 m spacing along the roads. There was no special effort to sample the cleanest marble, but from later examination of the sample sites, it can be assumed that the marble sampled in the early part of the project is better than average for the sampled outcrop.

The marble belts were located by the use of existing geological maps: Map 2031, Ashby Township (Evans 1964); Map 51d, Grimsthorpe–Kennebec Area (Meen and Harding 1942); Map 1362A, Carleton Place (Reinhardt *et al.* 1973); Map 2142, Cashel Township (Lumbers 1968); Map 2019, Chandos Township (Shaw and Hewitt 1962); Map 1956-4, Clarendon–Dalhousie–Darling Area (Peach and Smith 1956); Map 2049, Denbigh Township (Evans 1964); Map 1955-8, Dungannon and Mayo Townships (Hewitt and James 1956); Map 2054, Gananoque Area (Hewitt 1964a); Map 27-1962, Gananoque (Wynne-Edwards 1962); Map 2106, Lake Township (Laakso 1968); Map 2167, Limerick Township (Lumbers 1969); Map 2053, Madoc Area (Hewitt 1964a); Map 2154, Madoc Township (Hewitt 1968); Map 560A, Marmora Township (Wilson 1940b); Map 1960e, Methuen Township (Hewitt 1960); Map 1947-5, Olden–Bedford Area (Harding 1951); Map 1089A, Perth (Wilson and Dugas 1961); Map 2168, Tudor Township (Lumbers 1969); Map 1182A, Westport Area (Wynne-Edwards 1967); Map 770, Haliburton–Bancroft Areas (Adams and Barlow 1910); Map 1957-1, Cardiff and Faraday Townships (Hewitt 1959); Map 1957B, Haliburton–Bancroft Area (Hewitt and Satterly 1957); Map 1363A, Arnprior (Hill *et al.* 1974); Map P.2487, Ardoch Area (Pauk 1982, 1987); Map 1956-4, Darling and Lavant Townships (Peach 1958); Map 52A, Haliburton Area (Satterly 1943); Map 559A, Madoc Area (Wilson 1940a); Map 2432, Kaladar Area (Wolff 1982a); Map 2449, Long Lake Area (Wolff 1982b).

Locations were selected for detailed mapping on the basis of total weight percent CaO, MgO, and combined SiO_2 plus Al_2O_3. Only those areas containing samples with greater than 54 weight percent CaO, less than 4 weight percent MgO, and less than 1 weight percent combined SiO_2 plus Al_2O_3 were mapped for high calcium carbonate potential. Areas with high dolomite potential were selected based on the ratio of CaO to MgO, with only those areas containing samples with the CaO/MgO ratio between 1.4 and 1.7 and with SiO_2 plus Al_2O_3 less than 1.5 weight percent being mapped.

Detailed map areas vary in scale depending on the number of samples at each site. Maps were drawn by plotting roads and trails and making pace and compass traverses from these roadways or from other known locations.

The locations of detailed map areas have been plotted on the charts accompanying this publication (*see* back pocket), or for more detailed locations the samples have been plotted on NTS maps (scale 1:50 000) on file at the Resident Geologist's Office, Southeastern District, Tweed.

Geochemistry

ANALYTICAL METHODS

The majority of samples discussed in this publication (Part 1 data set) were submitted as pulps and analyzed by the Geoscience Laboratories of the Ontario Geological Survey, Toronto. The pulps for these samples were prepared in Tweed using a rock crusher and grinder under less than ideal laboratory conditions. For this reason some small inconsistencies in sample analyses have arisen. However, this does not affect the total CaO and MgO contents, which are of primary interest.

Nineteen elements were analyzed; in addition, the Loss on Ignition (LOI) was also determined. Major element contents were determined by X-ray fluorescence using a procedure developed for carbonate rock types (Papertzian and Kingston 1982a). This procedure allows for a complete range of MgO and CaO contents; however, marbles containing an abundance of impurities such as SiO_2, Al_2O_3, and total Fe_2O_3 may have quantities which fall outside of the calibration ranges. Calibration ranges for the major elements are indicated in Table 1.

Trace element contents were measured by a flame atomic absorption spectrometer. In the case where the trace element content is very high, the results of the analysis are given in weight percent rather than parts per million.

Detection limits for trace elements are indicated in Table 2.

Part 2 data set samples were analyzed by Barringer Magenta Limited under the direction of the Geoscience Laboratories of the Ontario Geological Survey. Major and trace element contents were determined using an Induced Couple Plasma (ICP) Spectroscopy System. This procedure involves the acid digestion of sample pulps while retaining solubles, then the testing of precipitates from solution by optical emission with the spectrometer to give the type and amount of element present. This method eliminates some of the problems of grind size encountered using rock powder pellets and X-ray Diffraction Spectroscopy (Riddle 1983). In addition to the 19 elements analyzed for Part 1 data set, F, S, Th, U, Mo, Ag, Be, Cd, and Zr were also determined for Part 2 data set. All channel samples collected (sample numbers ending in v, w, x, y, or z) were also tested for percentage reflectivities.

Detection limits are identical for the Barringer Magenta Limited and Ontario Geological Survey analyses for all trace elements with the exception of Ba, which has a detection limit of 30 ppm for the former. Major elements for Part 2 data set were analyzed with a complete calibration range, eliminating the possibility of having samples with elemental abundances above the calibration limit.

A complete set of chemical data for data Parts 1 and 2 are included in Appendix A.

DATA PROCESSING—ASSUMPTIONS

The nature of the data sets required that certain assumptions were made before the data was processed. Since data came from two separate laboratories, these data sets (Parts 1 and 2) were examined separately and were not collectively subjected to an averaging process in order that any discrepancies in analytical procedure or results would not affect the other set.

Only one sample, sample 1525b, was omitted from the total data set. Sample 1525b is a high-grade sphalerite sample and not a regional carbonate sample.

The large number of samples making up the data base (1912), combined with a minimum of 19 separate elements analyzed for each sample, has

TABLE 1. CALIBRATION RANGES FOR MAJOR ELEMENT ANALYSES OF SAMPLES.

Co	5 ppm
Cr	5 ppm
Ba	10 ppm
Li	3 ppm
Sr	10 ppm

provided over 36 000 individual chemical analyses. The simple statistical calculations and plots are collectively intended only as a tool in understanding the data more fully.

The samples have been divided into a number of subsets based mainly upon their calcium, magnesium, and silica contents (*see* Figures 4 to 18). Chemical data for samples in each subset, or classification, were examined statistically to determine anomaly levels for specific elements, and to determine the relationships between the various elements. Individual element geochemistry map plots showing the geographical distribution of samples with anomalous levels of elements (*see* Figures 19 to 27) were useful in crudely defining areas of marble with anomalous elemental contents. Of greatest interest is the identification of high-quality marble with good economic potential.

Most of the elemental populations displayed a skewed distribution making it necessary to perform logarithmic transformations to normalize the data sets. Since many of the samples contain 0.00 weight percent for various elements, it was necessary to add 0.01 weight percent to many of the major elements (Na_2O, K_2O, TiO_2, MnO, and P_2O_5) in order that logarithmic transformations could be made. The only elements not needing a logarithmic transformation were CaO and MgO, as these elements displayed a normal, although bimodal, distribution.

Many of the samples have analytical values which fall outside of the range of instrument calibration or below the detection limits. Analyses with values below the respective detection limits have values of one half the detection limit assigned to them. Values above the calibration limit have an arbitrary value, slightly higher than the calibration limit, assigned to them (Table 3).

MARBLE GEOCHEMISTRY

There are many different methods of classifying calcium carbonate rocks. One of the most basic subdivisions is between unmetamorphosed carbonate sedimentary rocks and their metamorphosed marble equivalents. Within the marble group, classification may be further subdivided on the basis of texture, colour, type of metamorphism (contact versus regional), and geochemistry. One universally applied method of geochemical classification for all types of calcium carbonate rocks uses the ratio of CaO to MgO (CaO/MgO). Putting titles on the different carbonate rock types is somewhat arbitrary since the theoretical limits of CaO/MgO range from 1.39 (the ratio of ideal calcite to ideal dolomite) to infinity. The ratio of CaO to MgO can be converted to percent calcite and percent dolomite using the following equations:

$$\%\text{calcite} = \frac{100\frac{\text{CaO}}{\text{MgO}} - 139}{1.17 + \frac{\text{CaO}}{\text{MgO}}}$$

$$\%\text{dolomite} = 100 - \%\text{calcite}$$

These equations assume that the sample is composed of 100% calcium carbonate.

The geochemical classification used in this publication (Figure 4b) is an adaptation of the Ontario Geological Survey classification of unmetamorphosed carbonate sedimentary rocks (Figure 4a), and was used previously by Storey and Vos (1981). Samples are classified into one of four categories, based on geochemistry: dolomite marble, calcitic dolomite marble, dolomitic calcite marble, and calcite marble. This is a quantitative classification and contrasts with the qualitative field classification described earlier and used for the purpose of geological mapping.

Figure 5 shows the observed frequency distribution of marble composition in percent calcite for Part 1 data set samples (1778 samples). Percent calcite is calculated using the formula given above and ranges from 100 percent, the ideal composition of calcite ($CaCO_3$), to 0 percent, the ideal composition of dolomite ($CaMgCO_3$).

The histogram shows a bimodal distribution with two peaks, one falling in the dolomite marble classification and the second in the dolomitic calcite marble classification.

The bimodal distribution displayed in Figure 5 is also evident in the frequency histogram showing marble composition in percent calcite for Part 2 data set reconnaissance samples (Figure 6), although because fewer samples are represented, the bimodal distribution is less obvious. This suggests that marbles in the Faraday and Chandos townships area, where the Part 2 data set samples were collected, show a similar range and pattern of chemical composition as marbles in the whole of the study area.

Figure 7, the frequency histogram showing marble composition in percent calcite for channel samples taken in the detailed map areas (Part 2 data set), is unimodal with most samples falling in the

TABLE 3. VALUES ASSIGNED TO ANALYSES BELOW THE DETECTION LIMIT AND ABOVE THE CALIBRATION LIMIT.

SiO_2	greater than 16 weight percent	20 weight percent
Al_2O_3	greater than 4 weight percent	5 weight percent
Fe_2O_3	greater than 7.5 weight percent	10 weight percent
Na_2O	greater than 2.5 weight percent	3 weight percent
K_2O	greater than 1.8 weight percent	2 weight percent
Co	less than 5 ppm	3 ppm
Cr	less than 5 ppm	3 ppm
Cu	less than 5 ppm	3 ppm
Li	less than 3 ppm	2 ppm
Ni	less than 5 ppm	3 ppm
Pb	less than 10 ppm	5 ppm

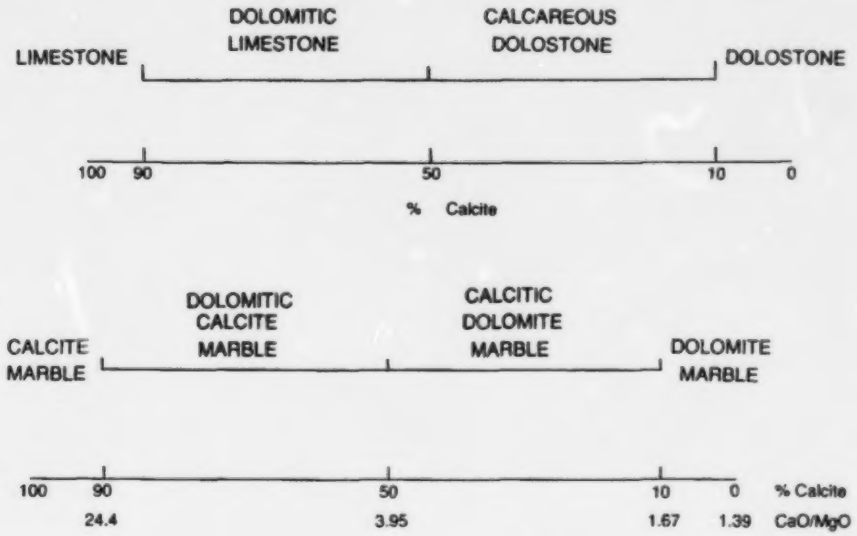

Figure 4. *Calcium carbonate and marble classification systems as used by Storey and Vos (1981). (a) Ontario Geological Survey calcium carbonate classification system. (b) Storey and Vos (1981) marble classification system.*

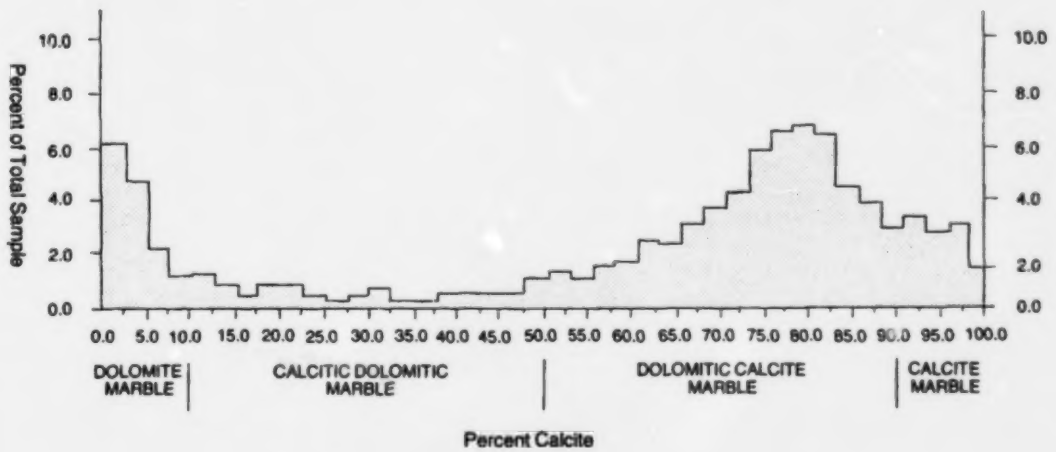

Figure 5. *Frequency histogram showing marble composition in percent calcite for Part 1 data set (1778 samples).*

range 75 to 87.5 percent calcite. The relatively narrow range of sample compositions of this group reflects the nonrandom sampling of potentially high-calcium marbles selected for detailed area mapping. The frequency histogram thus differs significantly from that of the total population of marble samples.

A bimodal distribution is observed in the frequency histogram of weight percent MgO (Figure 8) for Part 1 data set samples. The frequency histogram for weight percent MgO shows two major groupings of marble: a) the grouping in the 19 to 21 weight percent MgO range, which corresponds to the dolomite marble classification on the percent calcite frequency histogram of Figure 5; and b) the grouping in the 3 to 5.5 weight percent MgO range, which corresponds to the dolomitic calcite marble classification on the percent calcite frequency histogram of Figure 5. The frequency histogram for weight percent CaO (Figure 9) also shows a bimodal distribution, where the peak from 24 to 32 weight percent CaO is representative of a dolomite marble type, and the peak in the range 50 to 56 weight percent CaO corresponds to the dolomitic calcite marble type.

Figures 8 and 9 indicate the ideal compositions of calcite marble and dolomite marble such that a comparison of ideal compositions can be made with the observed compositions of samples classified as dolomitic calcite and dolomite marbles. Pure dolo-

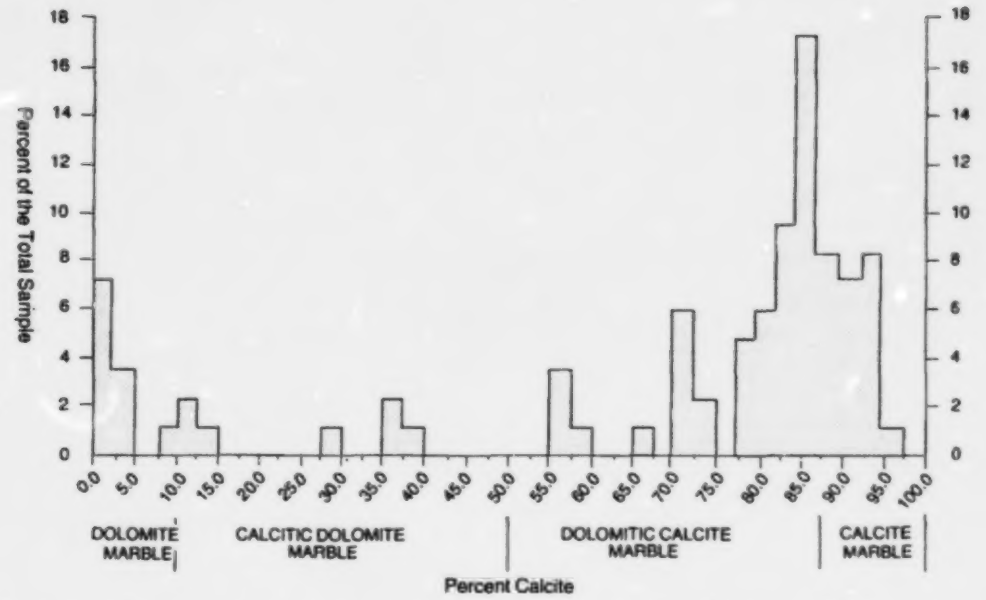

Figure 6. *Frequency histogram showing marble composition in percent calcite for Part 2 data set (82 samples).*

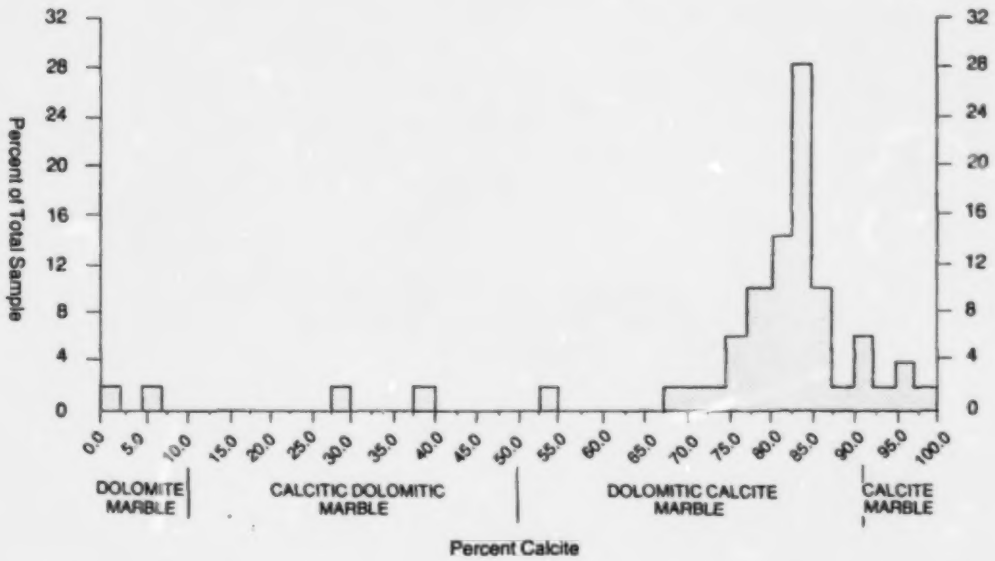

Figure 7. *Frequency histogram showing marble composition in percent calcite for Part 2 data set (50 channel samples).*

mite marble has an ideal MgO content of 21.6 weight percent and an ideal CaO content of 30.4 weight percent; pure calcite marble has an ideal CaO content of 56.0 weight percent and an ideal MgO content of 0.0 weight percent. Differences between the ideal values and the observed pure member compositions may be due to metamorphic effects causing the loss of CO_2 from the marble.

Figures 10 and 11 show, respectively, the observed frequency distribution of weight percent MgO and CaO, for the subset of "pure" dolomite marble samples, with weight percent SiO_2 less than 5, for Part 1 data set. Observed maxima compare closely with ideal values, suggesting that low-silica samples include those that have been unaffected or only slightly altered by the effects of metamorphism.

Figure 12, the frequency histogram for all samples in the pure calcite marble classification (CaO/MgO>24.4, SiO_2<5 percent) shows a relatively wide range of CaO content for pure calcite marble. The

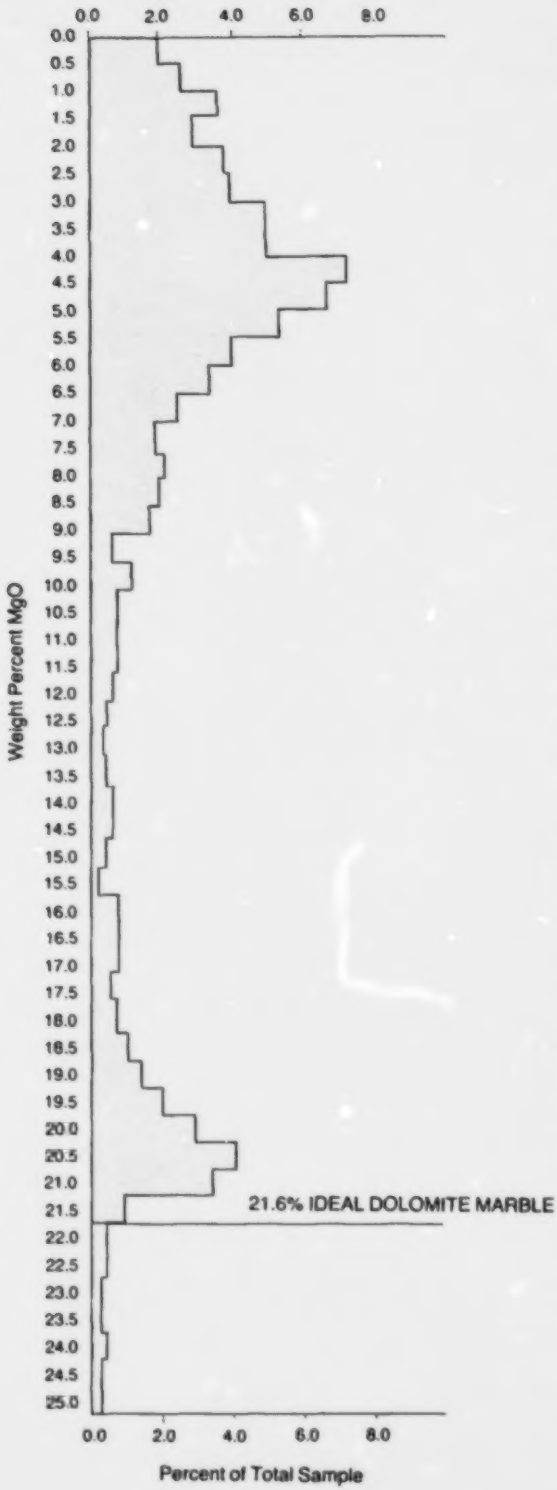

Figure 8. *Weight percent MgO frequency histogram, Part 1 data set (1778 samples).*

upper limit of 62 weight percent CaO for samples in this classification (6 weight percent above the ideal value) may be due to problems with the analytical method and/or loss of CO_2 during metamorphism resulting in a relative increase in CaO content.

Aside from the weight percent of CaO and MgO in a sample, one of the major factors influencing the potential value of a marble resource for industrial use is the abundance and type of contained impurities; the lower the impurity content, the better the marble. SiO_2 is generally the most abundant impurity in marble, with lesser amounts of Al_2O_3, Fe_2O_3, Na_2O, and K_2O being directly related to the amount of SiO_2 present.

Calc-silicate minerals present as impurities in marble are commonly formed as the result of either regional or contact metamorphism. These silicate minerals themselves often contain quantities of CaO and MgO as part of their chemical composition, which affects the overall ratio of CaO to MgO for the sample. If the metamorphic process was an open system, that is, a system in which elements such as SiO_2 have migrated in and out of the carbonate material, the elemental ratios are affected even more. This may result in some samples having a ratio of CaO to MgO of less than 1.39 (the ideal value for pure dolomite marble) which is not theoretically possible. A qualitative assessment of the data indicates that the MgO content remains relatively constant for a marble which has undergone silica enrichment during metamorphism; however, the CaO content decreases below the ideal composition of 31.4 weight percent CaO in dolomite marble, to between 24 and 26 weight percent (Figure 13). A number of other samples on this figure fall in the 8 to 20 weight percent range. These samples are not marbles but are actually carbonaceous metasediments.

TERNARY DIAGRAMS

Since SiO_2 content plays a key role in determining the potential of a particular marble for industrial use, it is necessary to include silica in the classification system. Storey and Vos (1981) used a CaO-MgO-SiO_2 ternary diagram (Figure 14) to classify the marble based upon the percentage of these three components, each normalized to 100 percent.

The numbers within the different blocks in the diagram correspond to the separate marble classifications (Table 4).

Categories 13 through 16 include all samples between 0 and 100 weight percent SiO_2 for a given ratio of CaO to MgO (Table 4), and as such are independant of SiO_2 content.

Each of the 19 elements in the analytical results (Part 1 data set) for 14 of the 16 marble types in Table 4 were examined statistically for the mean, standard deviation, error of the mean, skewness, kurtosis, maximum, minimum, and coefficient of variation (Appendix B). Categories 9 and 12 were

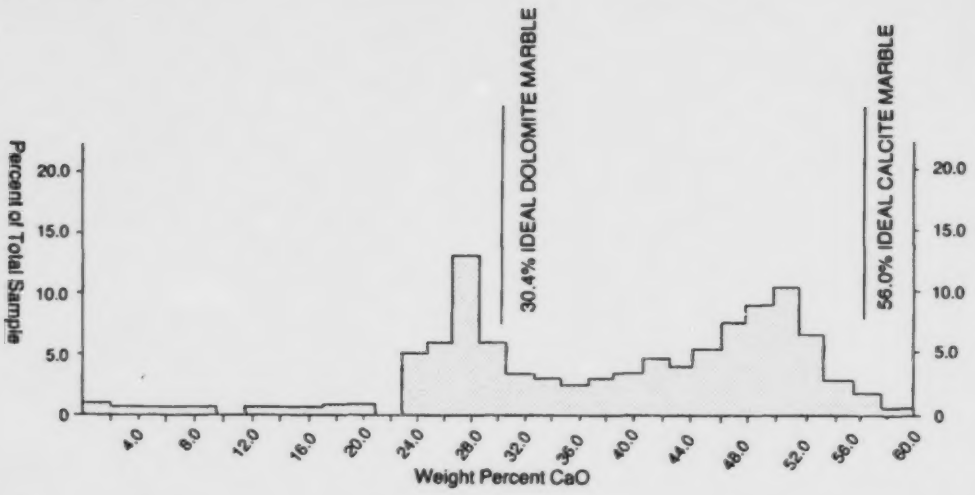

Figure 9. *Weight percent CaO frequency histogram, Part 1 data set (1778 samples).*

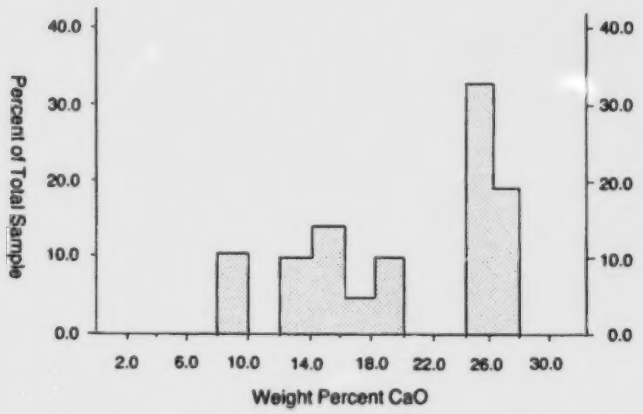

Figure 13. *Frequency histogram showing observed weight percent CaO content for calc-silicate calcitic dolomite marbles, Part 1 data set; samples with greater than 35 weight percent SiO_2 and CaO/MgO less than 1.67 (21 samples).*

not studied owing to the small number of samples within the groups, and the associated statistical errors involved in examining such a small population. The "non-marble" and "MgO greater than pure dolomite marble" categories, which are actually calcareous sedimentary or calc-silicate rocks, were not analyzed statistically because the focus of the study was on marbles.

The ternary diagram used in this publication differs slightly from the one used by Storey and Vos (1981) in that the SiO_2 content dividing siliceous from calc-silicate marble is adjusted upward to 35 percent from the arbitrary 31 percent value chosen by Storey and Vos (1981), such that all of the data plots below the calc-silicate field if all samples with greater than 20 percent SiO_2 are not included (Figure 15).

TERNARY DIAGRAM RESULTS

The ternary diagram for Part 1 data set (Figure 16) indicates a wide scatter in sample geochemistry. Groupings occur in the dolomitic calcite marble (No. 14) and dolomite marble (No. 16) fields with an obvious depletion of samples in the calcitic dolomite (No. 15) field. The 20 percent maximum calibration limit imposed on SiO_2 analyses has resulted in an anomalous set of sample compositions falling closer to the MgO apex than expected (Figure 16). This effect is minimized in Figure 17, where the chemical compositions of samples with SiO_2 greater than 20 weight percent were arbitrarily recalculated by setting the total weight percent to 100 percent and subtracting the weight percent of all other major elements as well as the Loss on Ignition (LOI), the remainder being the SiO_2 content plotted. This is a

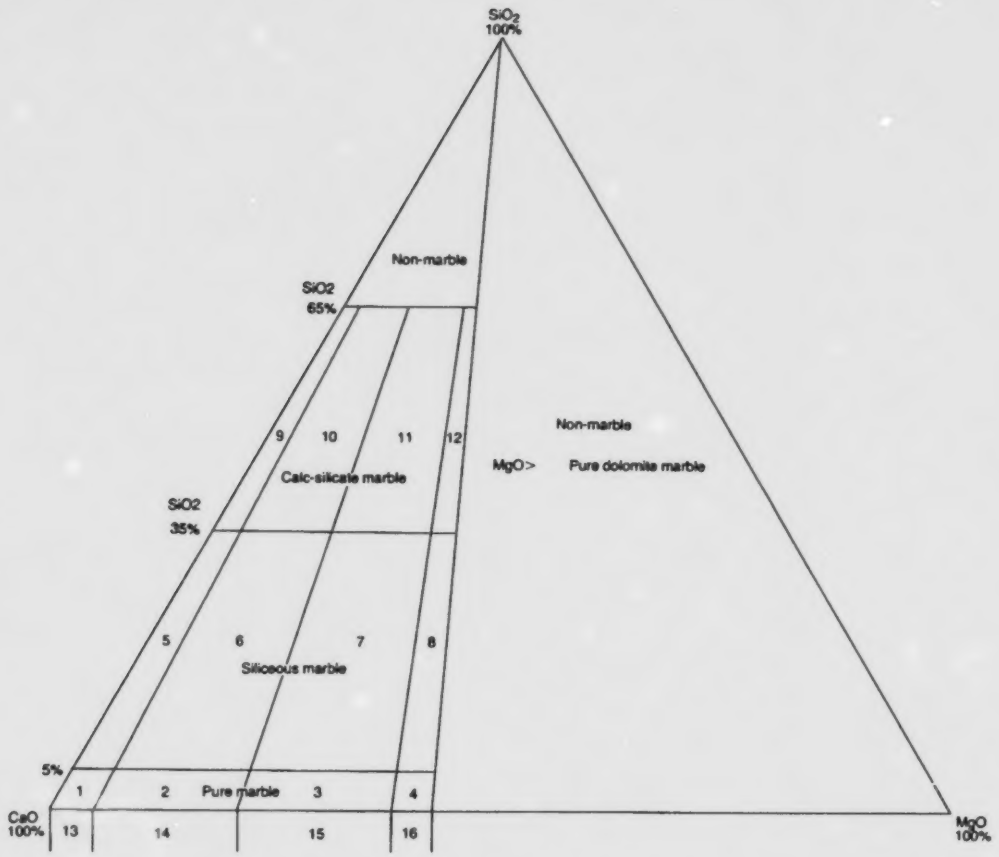

Figure 14. *CaO-MgO-SiO_2 ternary diagram classification system used in this publication (from Storey and Vos 1981).*

TABLE 4. MARBLE CLASSIFICATIONS AND NUMBER OF SAMPLES FOR CARBONATE ROCK TYPES.

Classification Name	$\frac{CaO}{MgO}$	SiO_2	Number of Samples
1. Pure Calcite	G.T. 24.4	0 - 5%	87
2. Pure Dolomitic Calcite	3.95 - 24.4	0 - 5%	450

TABLE 5. CLASSIFICATION OF MARBLES AND SYMBOLS USED IN THE CALCIUM-MAGNESIUM (CaO/MgO) RATIO MAP (FIGURE 20).

Lower Boundary CaO/MgO	Upper Boundary CaO/MgO	Classification	Symbol	Frequency
<1.400	1.400	non-marble	-	111
1.400	1.670	dolomite marble	1	243
1.670	3.950	calcitic dolomite marble	2	178
3.950	24.400	dolomitic calcite marble	3	1058
24.400	over	calcite marble	4/+	190

geologically reasonable method of treating the samples examined, since hand specimen and field notes revealed no other abundant minerals (for example, barite or fluorite) other than calc-silicate minerals.

Errors arise in this method when the totals of elements are greater than 100 percent causing SiO_2 to be a negative amount. These samples do not plot on the diagram but are represented by the symbol "v" on the bottom side of the triangle.

Part 2 data set samples were plotted on a separate ternary diagram (Figure 18). Since there are no imposed calibration limits on this data set there is a continuous range of SiO_2 to approximately 90 weight percent. As for Part 1 data set, there are two major populations of marble: a) dolomitic calcite marble; and b) dolomite marble.

Since this data set includes regional marble samples as well as 50 channel samples taken in potentially "clean" marble areas, the diagram is weighted somewhat toward samples high in CaO and low in SiO_2.

GEOCHEMISTRY MAPS

The major influence on the chemistry and relative purity of a marble is the original composition of the carbonate sediment. Environments of deposition of carbonate material generally occur on a large scale, suggesting that material will be consistent over a large definable area. By plotting the geochemistry of regional samples on a generalized grid of the study area, it is possible to delineate regions of different (high, moderate, or low) impurity content. The majority of carbonate units encountered during this study are unchanged chemically from typical premetamorphic limestone/dolostone precursors, although mineral assemblages may be variable due to differences in the metamorphic history of the belts.

The geographical distribution of Part 1 data set samples ("1" on the figure) and Part 2 data set samples ("2" on the figure) is shown on Figure 19. The northwest section of this map contains most of the Part 2 samples and corresponds to Faraday and Chandos townships (Chart A , back pocket).

Figure 20 is a plot of the spatial distribution of samples of the different marble classifications based on the calcium to magnesium (CaO/MgO) ratio of individual samples (*see* Table 5 for legend). An examination of this figure reveals that areas of high-calcium marble, high-magnesium marble, or some gradation between the two marble end members, exist. Exploration for end member marble types may be aided by concentrating efforts in those locations where the preferred marble composition exists.

Table 6 shows the 95th and 98th percentile values of the major oxide and trace elements analyzed. Those samples with analytical values above the 95th percentile—that is, only those samples with elemental compositions in the top 5 percent—are considered to be anomalous, and are plotted on individual

TABLE 6. MAJOR ELEMENT AND TRACE ELEMENT ANOMALY VALUES AS DETERMINED USING THE 95TH AND 98TH PERCENTILES.

	Percentile	
Element	95th	98th
SiO_2	20%	20%
Al_2O_3	5%	5%
Fe_2O_3	5%	5%

**Loss on ignition*

element "geochemistry maps" (*see* Figures 21 to 27).

Anomaly plots of weight percent CaO and weight percent MgO (Figure 21 and Figure 22, respectively) are useful in delineating calcite marble and dolomite marble zones. Samples with values above the 95th percentile are plotted as "1", while other samples are represented by "-".

The major factor which establishes the potential of a particular marble type for any industrial use is the content of impurities. Figure 23 is a plot of the silica (SiO_2) content where "1" represents those samples with greater than 20 weight percent SiO_2. All other samples are represented by "-". The map shows groupings of silica-rich zones displaying areas of low marble potential.

There is a strong direct correlation between the calcium (CaO) and strontium (Sr) contents of samples; the area of concentration of samples with anomalous Sr contents (Figure 24) coincides with the area of concentration of anomalous CaO samples (Figure 21). It is likely that the marine environment which formed the high-calcium carbonate rocks also contained high concentrations of Sr. Of further note, a higher proportion of samples with anomalous Sr contents (greater than 1330 ppm) falls in the southeastern corner of the map than anomalous CaO samples. It is known that aragonite accommodates Sr in the mineral lattice much more readily than Ca (Pettijohn 1975), and therefore it is possible that the areas with anomalous quantities of Sr originally consisted of aragonite-rich carbonate rocks.

Figure 25 is a plot of samples with anomalous zinc (Zn) contents (designated as "1" on the figure). These include all samples with Zn contents greater than 98 ppm (the 95th percentile).

Figure 26 is a plot of samples with anomalous copper (Cu) contents (greater than 25 ppm). The locations of these samples coincide quite well with those of marble samples containing high-silica contents (Figure 23).

Figure 27 shows the distribution of samples with anomalous lead (Pb) contents, that is, all samples with greater than 13 ppm Pb. The majority of these samples fall in the southeastern portion of the study area, in an area approximately 40 km south of Perth.

CORRELATION MATRIX

The Pearson linear correlation coefficient (Lavin 1988) is a statistical method of checking for linear relationships between two variables. A value of +1.0 indicates a perfect positive or direct linear relationship between two variables; for example, if one element in a sample increases by 50 ppm, then the other element also increases 50 ppm. A value of -1.0 indicates a perfect negative or inverse linear relationship; for example, if one element increases by 50 ppm, the other decreases by 50 ppm. A value of 0.0 indicates a lack of any correlation between the two variables. There is also a full range of correlation values between -1.0 and +1.0, all indicating less-than-perfect linear relationships.

Since correlation coefficients are only valid for normally distributed data, most of the elemental data were transformed logarithmically before the Pearson coefficients were determined. This was necessary since most of the data sets were strongly skewed toward the right. The size of the data set determined the accuracy of the correlation coefficient, therefore making the matrix of Part 1 data set (Table 7) more reliable than that of Part 2 data set (Table 8).

Part 1 Data Set Results

The strongest correlations in this matrix exist between the elements that make up the impurities in the marble. There are positive linear relationships between all of the following elements: SiO_2, Fe_2O_3, Al_2O_3, Na_2O, K_2O, TiO_2, Co, Cr, and Li. Weaker positive correlations exist between Cu, Ni, Zn, and MnO. Inverse relationships exist between CaO, MgO, and the contaminant elements. There is a strong inverse relationship between MgO and Sr, the latter of which shows a direct linear correlation with CaO, its analogue. There is also a strong positive correlation between CaO and LOI.

Part 2 Data Set Results

Correlation coefficients in this matrix are larger than those in Table 7; the same association between all of the elements making up the impurities exist, although they are more pronounced in this matrix. The same positive correlation between LOI and CaO, and the inverse relationship between Sr and MgO, is also a feature of this matrix.

Recommendations for Exploration

The total amount of Precambrian marble in the study area is very large, and it is beyond the scope of this publication to examine more than a small percentage of the total outcrop area. The sampling program and mapping covered only those areas that were readily accessible. Of the 1912 samples taken during the regional sampling only 82 samples had their immediately surrounding areas mapped, representing only 4.3 percent of the sampled outcrops. This means that there was extremely limited coverage of all of the marble in all of the townships mapped.

Most of the main marble belts have had at least one detailed area mapped within them. It is hoped that a study of the mapped areas can indicate which belts have the best potential for an economic marble deposit. However, it was evident as a result of the study that the marble changes dramatically, both chemically and mineralogically, over a relatively small area. Hence, detailed mapping of each belt may reveal areas of high-grade marble, even if the marble belt is composed mainly of marble of poor grade.

Many of the white marble units are associated either with an intrusion nearby, or are found in areas of high-grade metamorphism. Detailed geological mapping provides the information necessary to identify these target areas. The higher grade of metamorphism results in the recrystallization of the marble and very often, in a coarse grain size. Almost all of the fine-grained marbles, which are more suitable for building stone, are light to dark grey in colour.

Also of note is that pure marble, particularly calcite marble, is more susceptible than either dolomite or siliceous marble to weathering. Therefore, less pure marble outcrops extensively whereas pure marble is hidden by overburden. A certain amount of diamond drilling will be necessary to explore beneath the surface for the more pure marble, once an area of good economic potential has been located.

Marble Map Area Descriptions

Table 9 is a compilation of the symbols used in the marble map area figures. Rock names are also indicated. It should be reiterated here that for the purpose of geological mapping, marble was classified as either calcitic or dolomitic based on a simple acid test in the field. The geochemical classification described earlier is based on the geochemical analysis of samples collected and is not of relevance in this section.

Table 10 lists the townships which were inventoried during the course of the study. Townships which include areas which have been mapped in detail (*see* Figures 28 to 97) are indicated with an asterisk.

CALCITIC MARBLE MAP AREAS

Table 11 is a list of the calcitic marble map areas mapped during the course of the survey. Calcitic marble map areas were selected on the basis of the total weight percent of CaO, MgO, and SiO_2 of appropriate samples. Selected samples met the requirements of greater than 54 weight percent CaO, less than 5 weight percent MgO, and less than 1 weight percent SiO_2.

MAP AREA 31

Location

North-central Madoc Township.

Map reference: NTS 31C/12; UTM 301200mE, 4943450mN, Zone 18.

Access

Two kilometres east of Highway 62, on the first road south of Keller Bridge, Concession VII, Lot 22.

Regional Geology

This map location is situated within the large marble belt in Madoc Township. Amphibolite and para-amphibolite units, as well as metasediments, occur throughout the marble belt (Hewitt 1968).

Local Geology

The detailed map area is made up entirely of calcitic and dolomitic marble (Figure 28). Dolomitic units up to 50 m in width are oriented roughly parallel to

TABLE 9. LEGEND AND SYMBOLS USED FOR SAMPLE LOCATION MAPS (FIGURES 28 TO 97).

the marble foliation. Contacts between the calcitic and dolomitic units are sharp, suggesting that the dolomitic marble is part of the original sedimentary sequence and is not the result of metamorphic processes. Calcitic marble in the area is either fine grained and grey, with only minor amounts of visible phlogopite, or a less pure variety containing pyrite, phlogopite, and quartz, the latter as irregularly shaped clots and boudins.

Previous Geological Work

Madoc Township has been mapped by Miller and Knight (1914), Wilson (1940a), Hewitt and Satterly (1957), Hewitt (1964a), and Hewitt (1968).

Chemistry

Regional samples taken from within this marble belt (samples 9 to 46, Appendix A) show that much of the marble contains greater than 5 weight percent SiO_2. Many samples are dolomitic in composition, the majority of which contain low (less than 5 percent) SiO_2 contents. SiO_2 occurs locally as silica and silicate clots and bands through much of the dolomitic marble. Samples 35a and 35b (Appendix A) have anomalously high Cu and Co contents, while other samples in the belt have background levels of trace and metallic elements. Three locations in the detailed map area were channel sampled to test overall marble consistency. Each of the three channel samples 31x, 31y, and 31z, contains appreciably greater amounts of SiO_2 than the original sample 31, and consequently each has a lower CaO content. Reflectivity measurements on the three channel samples also give very low values due to the grey colour of the marble.

Potential

Although much of the marble in the map area contains a high SiO_2 content, detailed mapping of the belt has revealed local areas of high-quality marble. It is expected that other such zones occur throughout this marble belt.

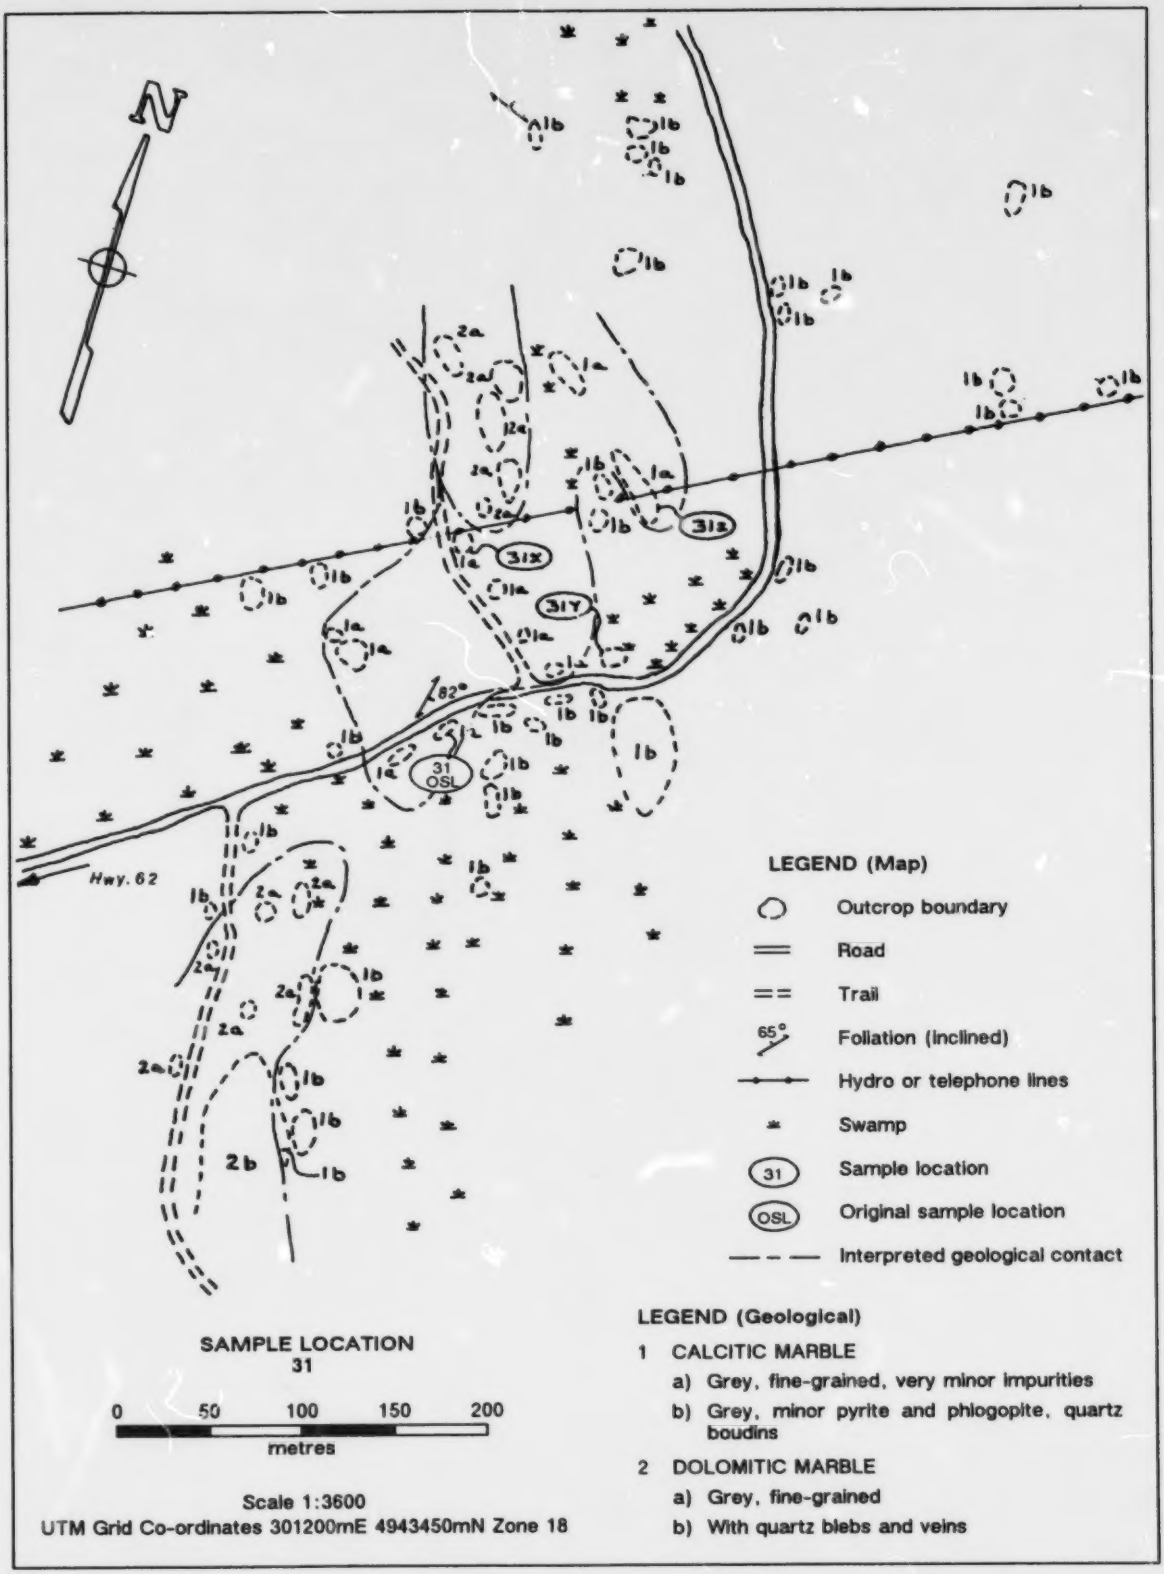

Figure 28. *Location Map, Sample 31.*

MAP AREA 104a

Location

North-central Tudor Township.

Map reference: NTS 31C/13; UTM 291700mE, 4965700mN, Zone 18.

Access

On Highway 62, 300 m south of Beaver Creek, Concession XVIII, Lot 16.

Regional Geology

This sample location is in a relatively narrow east-northeast-trending marble belt bounded by metasediments and metavolcanics. North and east of the marble belt a metasedimentary unit interfingers with the marble.

Local Geology

Detailed mapping (Figure 29) shows that there are several metasedimentary units within the main marble zone. The metasediments are similar to the marble in both texture and colour. Marble is predominantly dark grey with lighter grey laminations. Several zones of brecciation (Photo 3) occur in the area with considerable deformation near the breccia zones. Fracturing is common in the deformed marbles; fractures are filled with white calcite. Marble purity is generally very high with only minor amounts of pyrite visible.

Previous Geological Work

Tudor Township has been mapped by Hewitt and Satterly (1957) and Lumbers (1969).

Chemistry

Regional samples within this marble belt (samples 104 to 106, Appendix A) all contain high CaO contents along with low MgO and SiO_2 levels. Trace and metallic element contents are at or below background levels. Two channel samples, samples 104y and 104z, were taken to test marble consistency. Both samples have low SiO_2 and high CaO contents. The grey colour of the material results in an average reflectivity for the two samples of only 33 percent.

Photo 3. *Brecciated marble in map area 104a.*

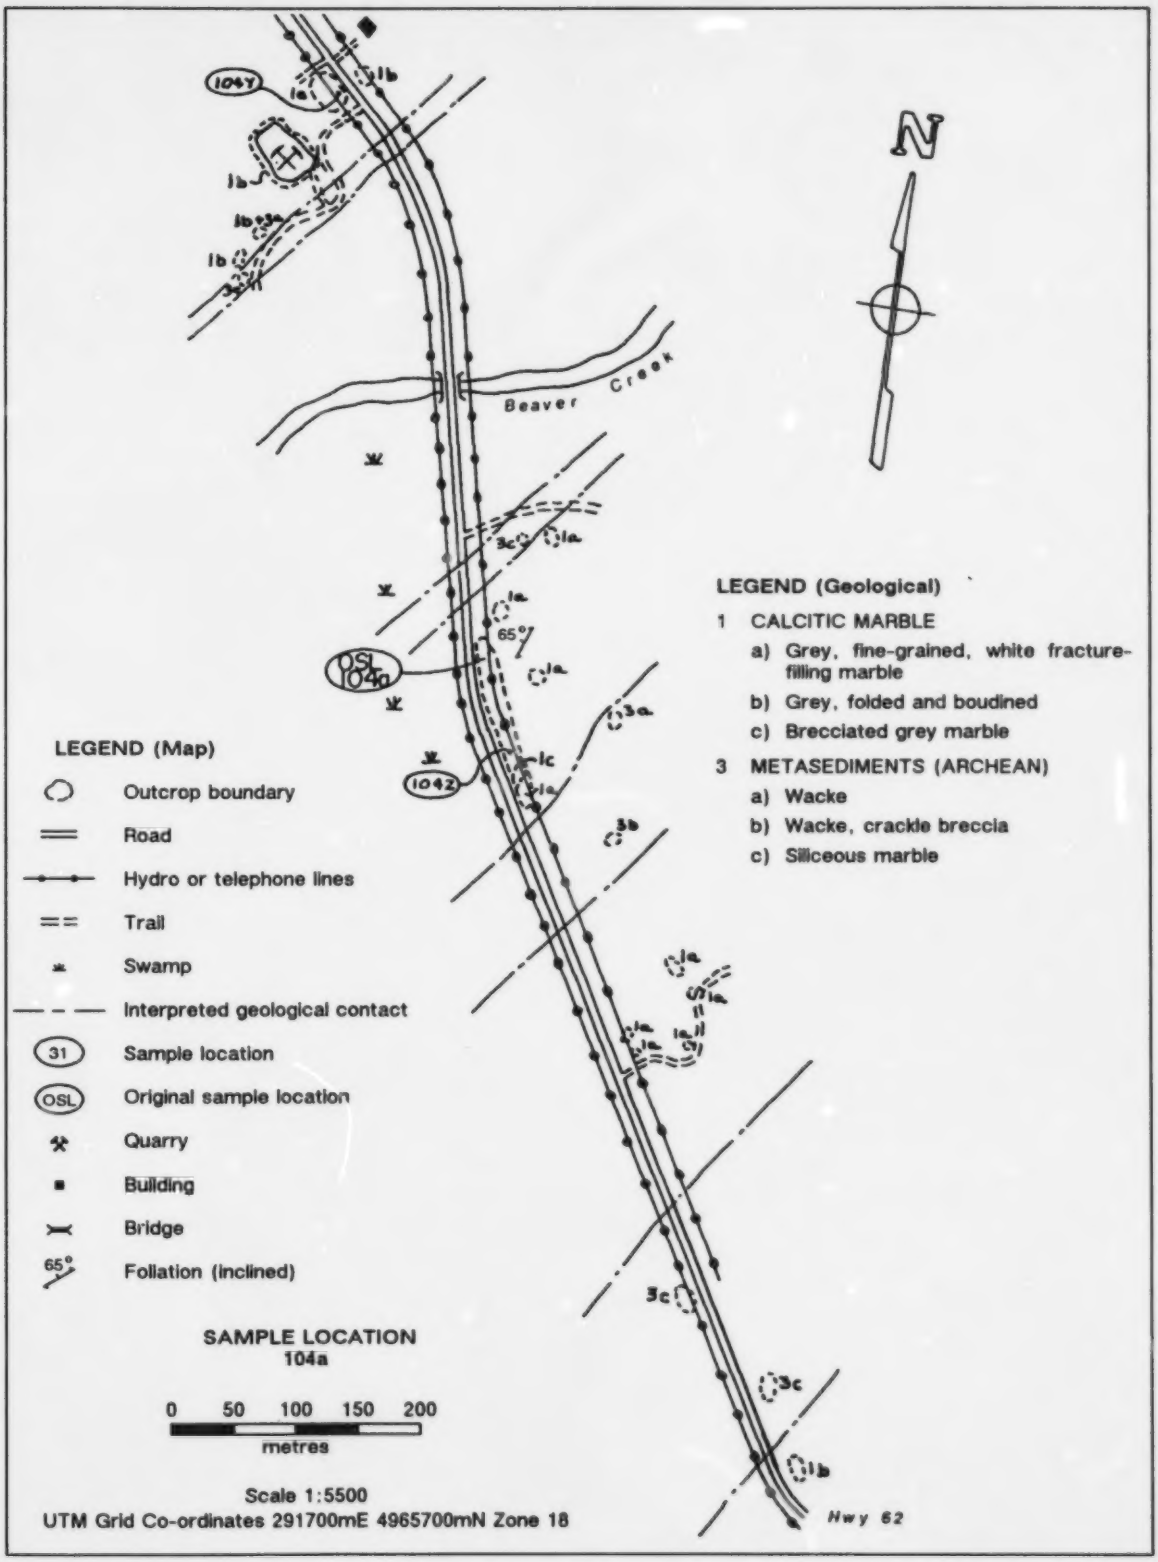

Figure 29. *Location Map, Sample 104a.*

MAP AREA 134/1308

Location

North-central Hinchinbrooke Township.

Map reference: NTS 31C/10.

134—UTM 356800mE, 4942450mN, Zone 18.

1308—UTM 356600mE, 4942350mN, Zone 18.

Access

Both samples were taken along a west-trending gravel road, 1.5 km south of Wagerville, Concession IX, Lot 19.

Regional Geology

These samples are from a narrow west-trending marble belt. The marble belt is near the southern edge of a much wider amphibolite unit, also trending west between the McLean Pluton and the Hinchinbrooke Complex (Wolff 1982b). This amphibolite complex is interpreted to be a metavolcanic sequence by Wolff (1982b).

Local Geology

Detailed mapping (Figure 30) indicates that marble is conformable with metavolcanics, metasediments, and igneous gneiss. Marble occurs as a single belt, while other units tend to repeat across strike. The carbonate material is dominantly white with shades of orange and buff colour, depending on the impurity content. Much of the marble contains serpentine, phlogopite, and muscovite with a close association between the presence of serpentine and orange-coloured marble. Locally, minor amounts of disseminated pyrite, along with calc-silicate clots, occur within serpentine- and phlogopite-bearing marble.

Previous Geological Work

Hinchinbrooke Township has been mapped by Harding (1951), Hewitt (1964a), and Wolff (1982b).

Chemistry

Regional samples in this marble belt (samples 134 and 1306 to 1308) indicate a fairly uniform, high CaO content with a low SiO_2 content. This is also evident in the two channel samples, which average 3.5 weight percent SiO_2 with approximately 50 weight percent CaO. Reflectivity measurements for the two channel samples are 70 and 77 percent.

Potential

The chemistry of individual marble samples suggests that there is a good potential for filler-type material throughout the entire belt. This is somewhat misleading due to the presence of calc-silicate clots locally and the interfingering of metasedimentary and metavolcanic units. Most of the marble is in fact rather impure and would require some type of beneficiation to provide a good marble product.

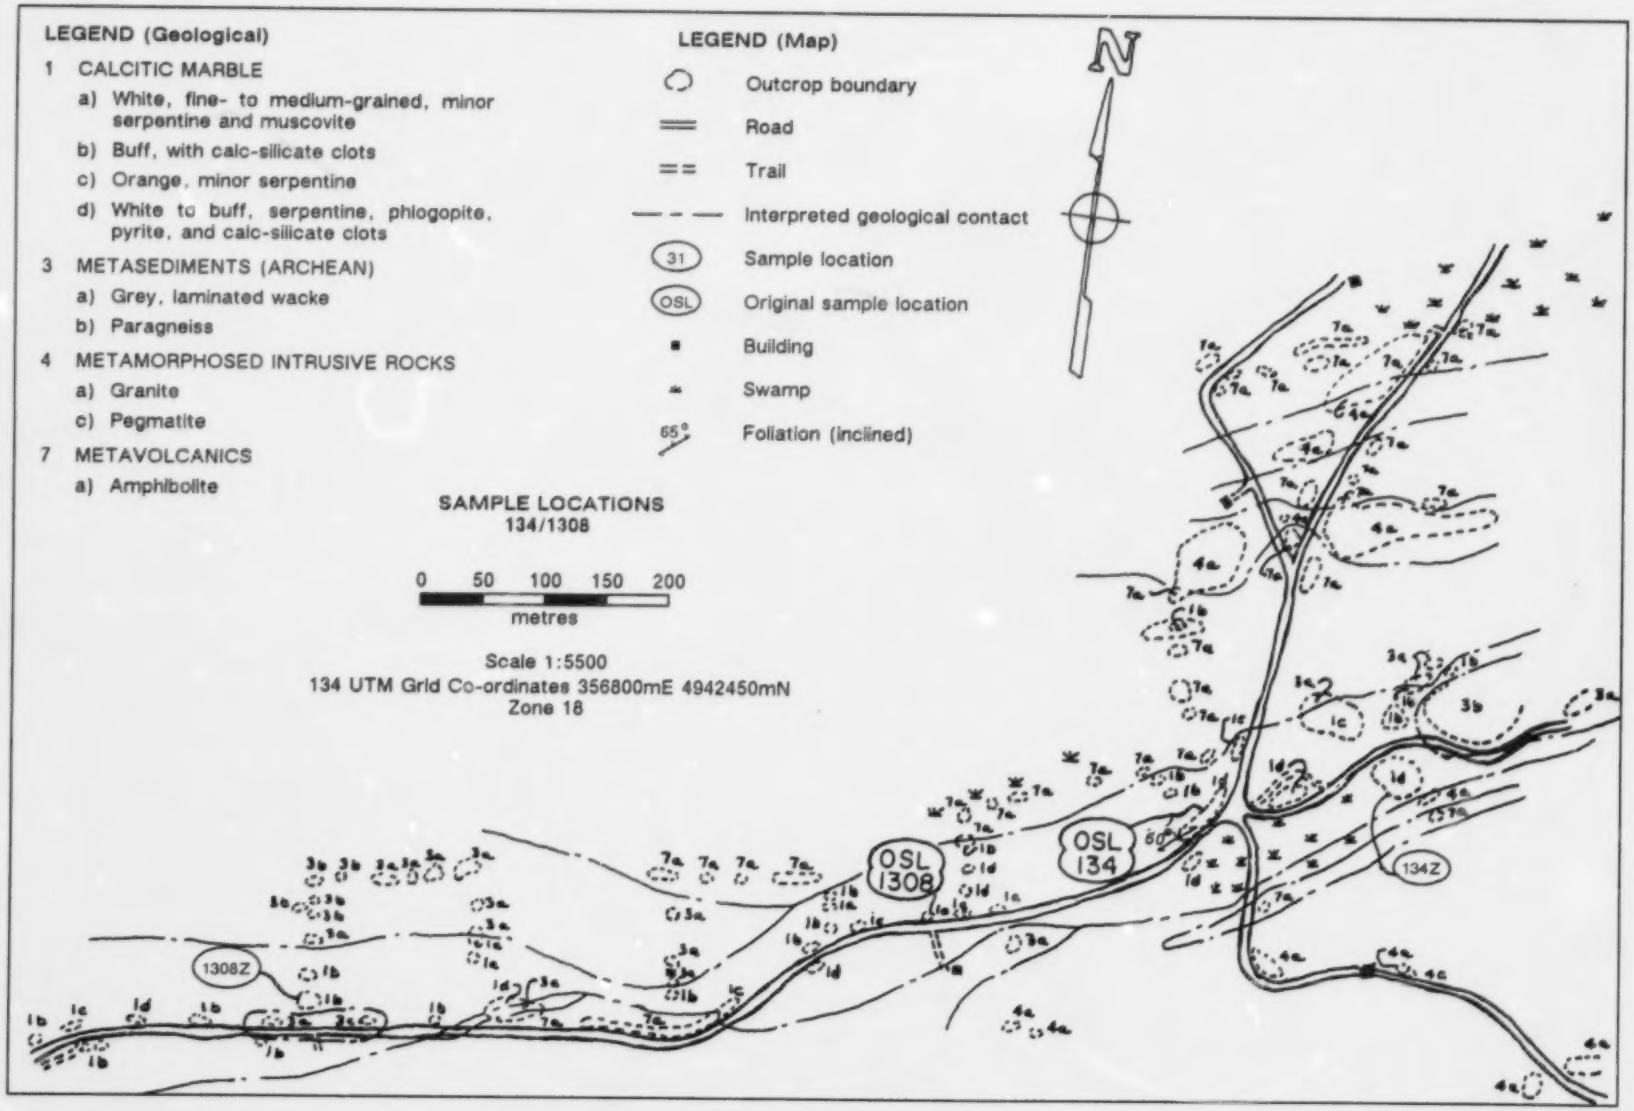

Figure 30. *Location Map, Samples 134 and 1308.*

MAP AREAS 244, 261, AND 265

Location

244—3 km north of St. Ola, Limerick Township.

261—4 to 4.5 km north of Gunter, Cashel Township.

265—2 km north of Gunter, west side of Gunter Lake, Cashel Township.

Map reference: NTS 31C/13.

244—UTM 293800mE, 4973000mN, Zone 18.

261—UTM 300850mE, 4979000mN, Zone 18.

265—UTM 299300mE, 4974600mN, Zone 18.

Access

244—On a poor one-lane road which runs up to the north end of St. Ola Lake, Concession V, Lot 8.

261—On a ministry access road, 4 km north of Gunter, Concession VIII, Lot 17.

265—On a new ministry access road, on the west side of Gunter Lake, Concession IV, Lot 25.

Regional Geology

All three sample locations are part of a large marble belt extending northeast through Limerick and Cashel townships. The area is crosscut by numerous faults with different orientations but with apparently little offset. The marble is dominantly light grey or grey laminated with a fine grain size. Accessory minerals include fine-grained graphite, pyrite, phlogopite, and tremolite. Regional metamorphism is in the greenschist to lower amphibolite range (Lumbers 1969).

Local Geology

244—Detailed mapping at this location (Figure 31) shows an area of fine-grained grey marble, commonly laminated with light and dark layers, and with very minor impurities. The impurities that are evident in the carbonate rocks are fine-grained pyrite and phlogopite. Within the map area are several small amphibolite units which are conformable to marble laminations.

261—The dominant lithologies occurring within this area are metasediments (amphibolite) and marble, the latter being the predominant rock type (Figure 32). These two units interfinger with one another across the local map area. Much of the amphibolite is coarse grained with calcite in the groundmass, and apparently is the metamorphosed equivalent of dirty calcareous sediments. The marble composition is highly variable across strike and therefore it is likely that it was originally composed of relatively thin beds. The presence of marble and metasediment breccias indicate that minor faulting has occurred across the map area.

265—The portion of the large marble belt from which this sample was taken is underlain by fine-grained grey laminated marble (Figure 33), very similar in appearance to the marble at sample locations 244 and 261. The material at sample location 265 contains very minor impurities. Muscovite occurs along foliation planes. Occurring across the map area are several narrow amphibolite units which are conformable to marble laminations. Lumbers (1969) has interpreted these units to be metamorphosed mafic sills. It seems more likely that these are metamorphosed calcareous sedimentary rocks which were originally interbedded with the limestone.

Previous Geological Work

Limerick Township has been mapped by Hewitt and Satterly (1957) and Lumbers (1969). Cashel Township has been mapped by Lumbers (1968), and in part by Hewitt and Satterly (1957) and Hewitt (1964a).

Chemistry

Regional marble chemistry in this belt (samples 235 to 276, 280 to 283, and 326 to 331) is highly variable across strike, with numerous metasedimentary units occurring within the carbonate rocks. The dominant marble type is calcitic marble, with only minor dolomitic marble. Trace and metallic element contents are very low throughout the entire belt. Channel samples within map areas 244 and 265 indicate higher SiO_2 contents than the original samples. The grey colour results in low reflectivities (43 percent, 48 percent, and 29 percent for samples 244y, 244z, and 265z, respectively).

Potential

The entire marble belt is composed of grey fine-grained marble with conformable metasediments. Certain marble zones have very high CaO contents, but the grey colour and presence of metasediments and amphibolite render the marble less than desirable as filler material.

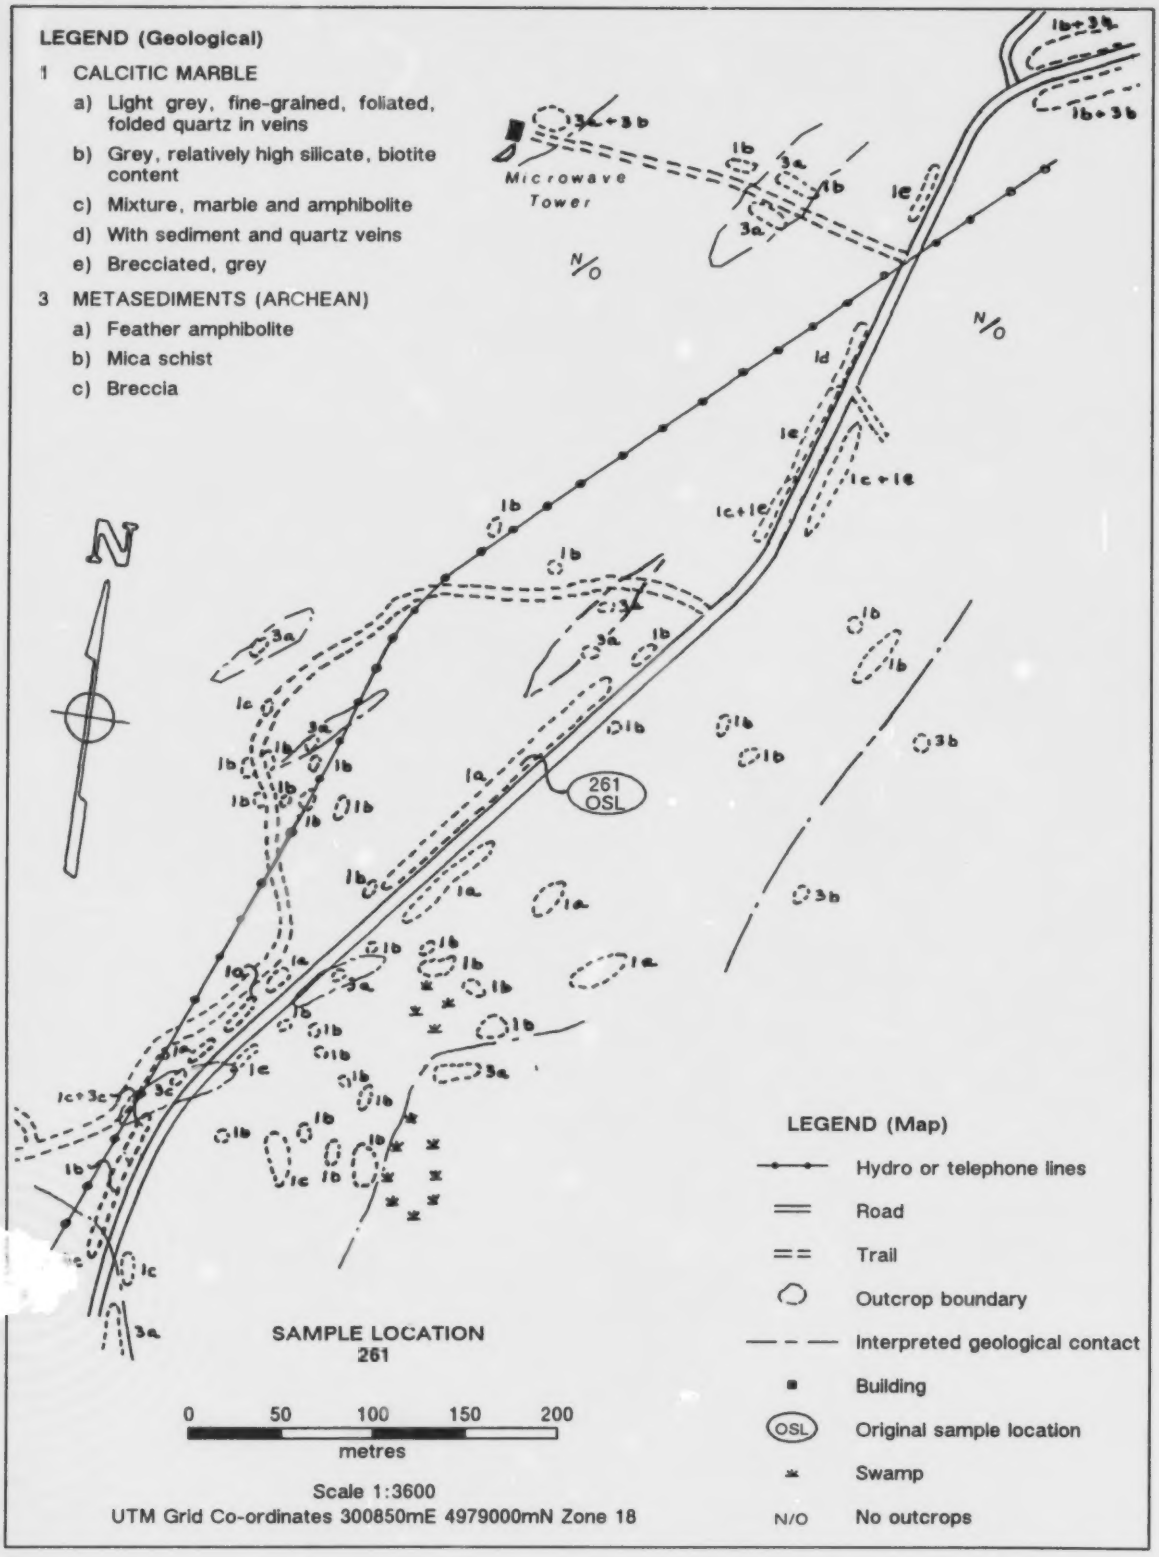

Figure 32. *Location Map, Sample 261.*

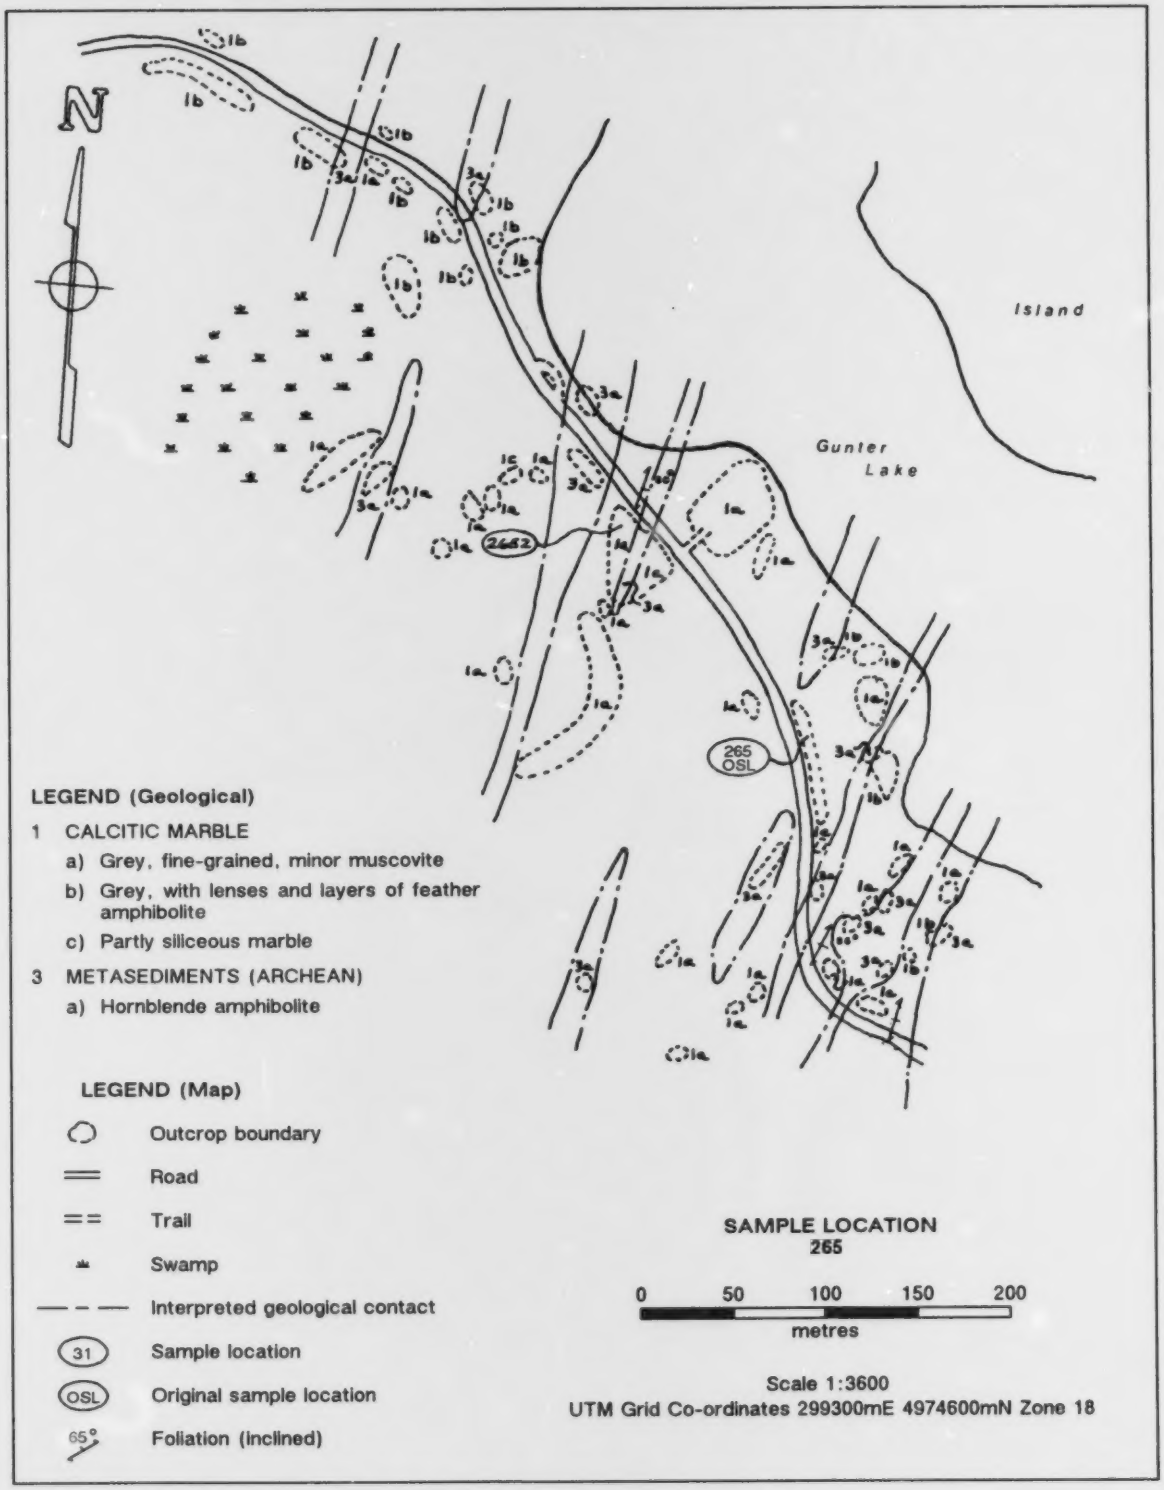

Figure 33. *Location Map, Sample 265.*

MAP AREAS 313 AND 401

Location

Mayo Township.

Map reference: NTS 31F/4.

313—UTM 295750mE, 4994920mN, Zone 18.

401—UTM 294850mE, 4991580mN, Zone 18.

Access

South on a gravel road from Highway 500 at New Hermon.

313—On Sharrow Lake, Concession VIII, Lot 15.

401—On Foster Lake, Concession VI, Lot 10.

Regional Geology

The marble belt from which these samples were taken crosses east-northeast through Mayo Township. The belt is bounded on both sides, and partially interfingers with, Hermon Formation metasediments (Hewitt and James 1956). Within the belt are several conformable metamorphosed mafic volcanic rock units. The metasedimentary and metavolcanic units are variable in thickness and length.

Local Geology

313—In the detailed map area (Figure 34), marble is predominantly light grey and fine grained with only minor impurities disseminated throughout. Interbedded with this marble variety are grey coarse-grained and grey laminated marble units.

401—Within this area (Figure 35) is a large paragneiss unit made up mainly of coarse-grained plagioclase and quartz crystals. Often there are large marble blocks contained within the paragneiss units, but the relationship between the two is difficult to determine. The marble appears to have flowed around and into the paragneiss, at times incorporating rafts of paragneiss into the marble. The marble is generally grey, fine grained, and contains local zones of amphibolite.

Previous Geological Work

Mayo Township has been mapped by Adams and Barlow (1910), Hewitt and James (1956), and Hewitt and Satterly (1957).

Chemistry

Much of the marble in this belt (samples 300 to 313 and 400 to 402) is relatively free of silica; however, the marble composition is variable. A large number of samples taken from this area are from dolomitic marble units, particularly toward the northeastern end of the belt. Samples 311, 312, 313, and 400, which come from units within the belt, have less than 2 weight percent SiO_2 and greater than 50 weight percent CaO (Appendix A). Trace and metallic element contents are below background throughout most of the belt. Channel samples taken in calcitic marble in map area 313 indicate a high SiO_2 content. Reflectivity, as expected, is only in the 50 percent range as the marble is grey.

Potential

The greyness of the marble and the presence of paragneiss and/or amphibolite in both of these areas make the marble unfavourable for filler material. Chemically the material has good qualities, and therefore with beneficiation the material may have some potential.

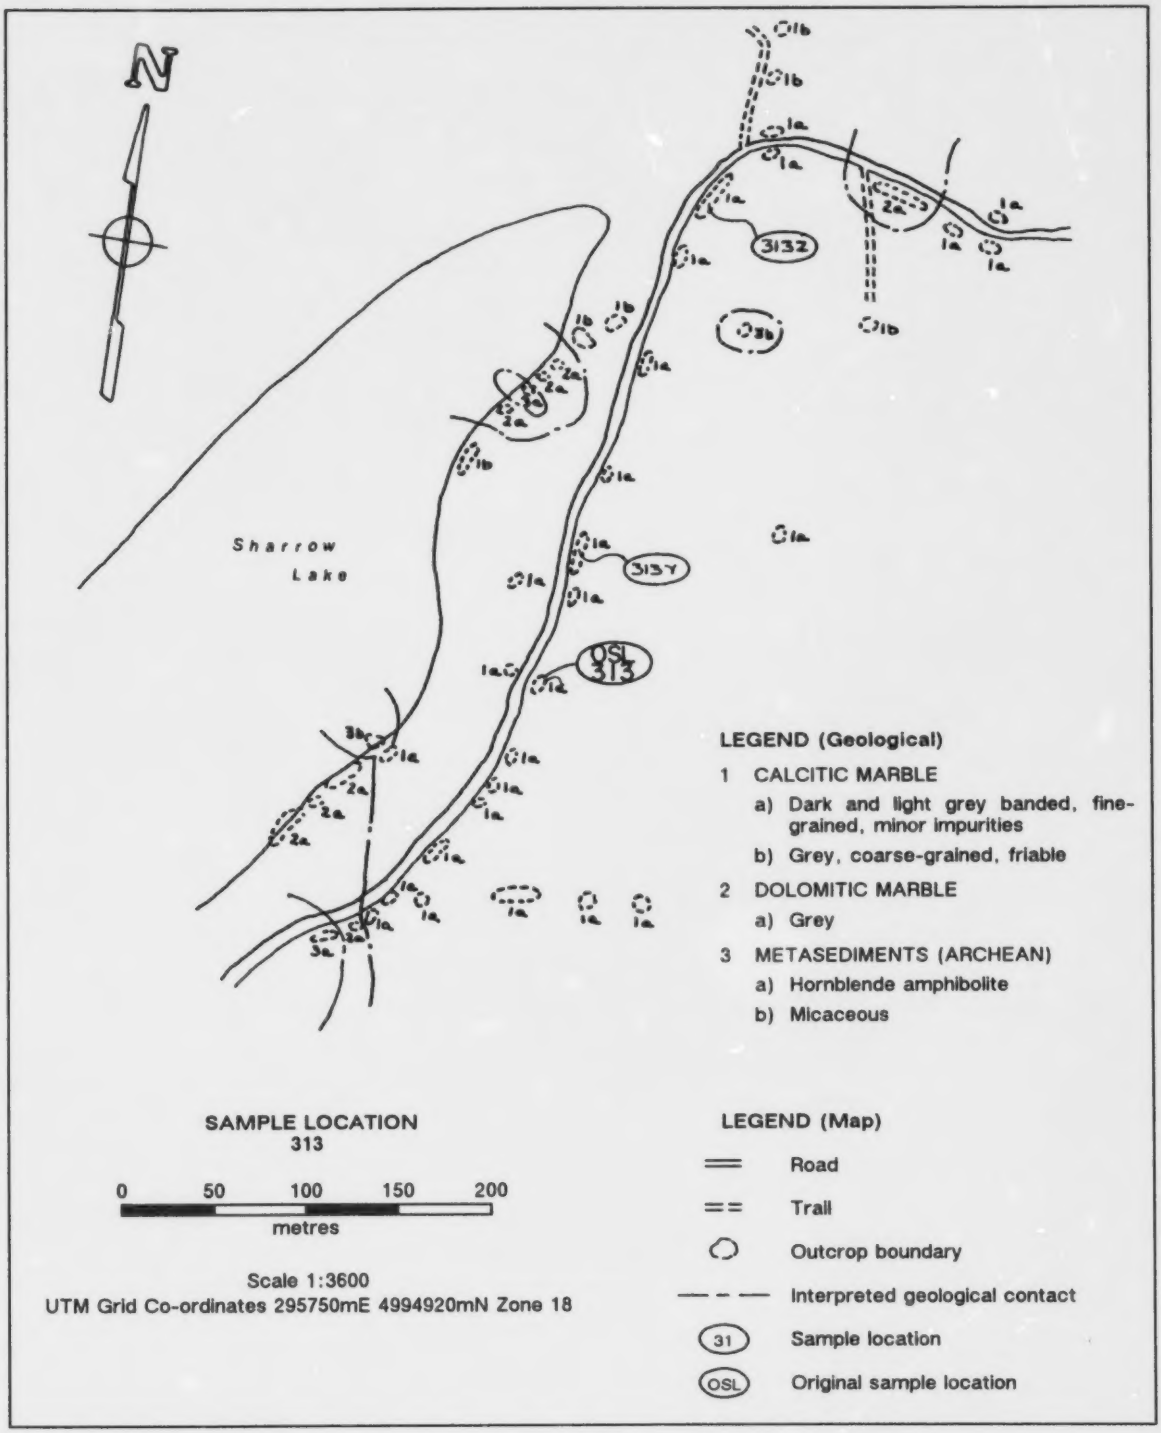

Figure 34. *Location Map, Sample 313.*

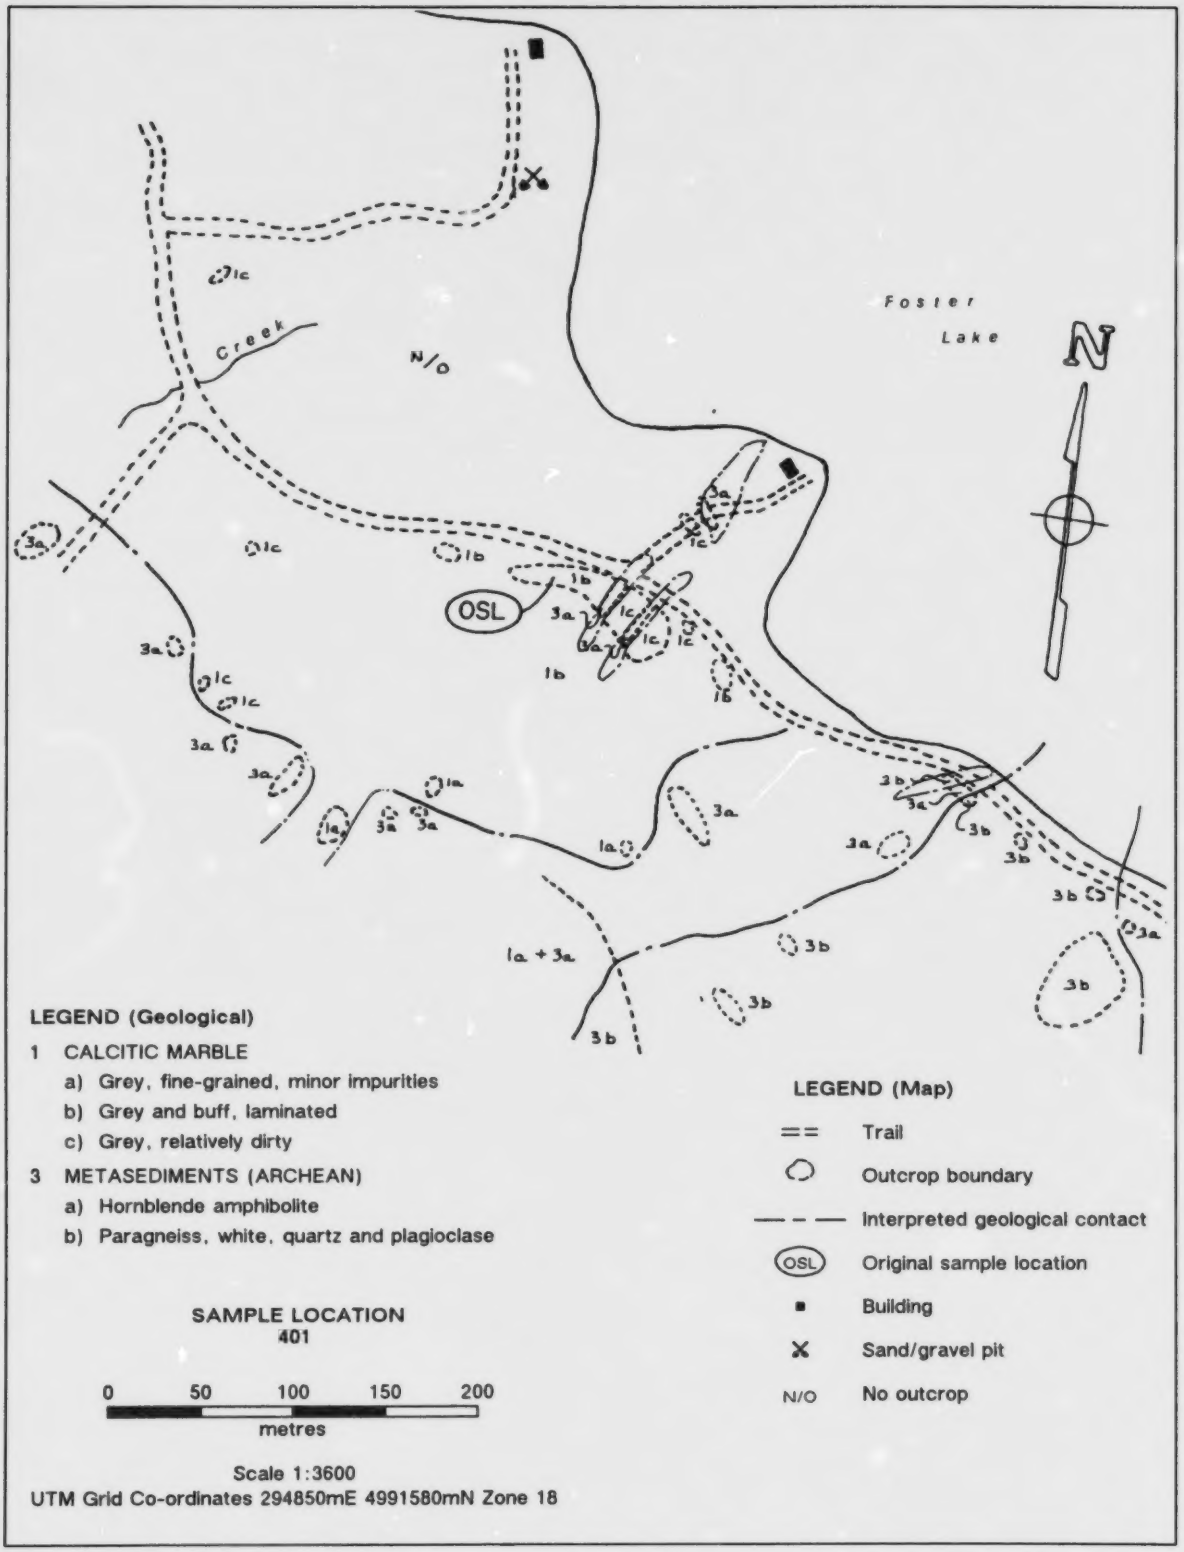

Figure 35. *Location Map, Sample 401.*

MAP AREA 347

Location

East-central Sheffield Township.

Map reference: NTS 31C/10; UTM 350150mE, 4936700mN, Zone 18.

Access

At a hunt camp along a narrow seasonal road, a few hundred metres northeast of the main gravel road and 200 m south of Slave Lake, Concession XV, Lot 11.

Regional Geology

Marble belts in this area are generally narrow and discontinuous, pinching and swelling within the host granitic rocks. Numerous occurrences of base metal sulphide minerals are within, or very near to, these marble zones.

Local Geology

Sample 347 was taken from the waste rock dump at the Lennox Mine Zinc Occurrence (Figure 36). Marble occurs both as long narrow bands and as wide discontinuous units. Sphalerite is contained within calcitic and dolomitic marble (Carter 1984). The marble is predominantly white with disseminated sphalerite, phlogopite, and pyrite. Contacts between the marble and the granite are generally sharp, often with an interfingering of the two. The total amount of marble covers an area of 300 m by 200 m.

Previous Geological Work

Sheffield Township has been mapped by Hewitt (1964a), and the Lennox Mine Zinc (Slave Lake) Occurrence has been mapped by Sangster (1970) as part of an unpublished MSc thesis, and by Carter (1984).

Chemistry

The sample taken at this location contains low amounts of trace and metallic elements, including zinc. Most of the samples taken from this marble belt (samples 1266, 1267, and 1300 to 1303) contain approximately 54 percent CaO and 5 percent MgO, with 1 to 2 percent SiO_2. None of the samples taken indicate higher than average amounts of Zn or any other metallic element. Two channel samples in this map area indicate SiO_2 contents of less than 1 percent. Reflectivity measurements for the two samples are 49 percent and 55 percent, respectively.

Potential

Marble in this area is good in colour and in CaO/MgO ratio. Impurities are disseminated and rarely total more than 2 percent. In the detailed map area marble tonnage is low, but more extensive marble units in the surrounding area may be of comparable quality.

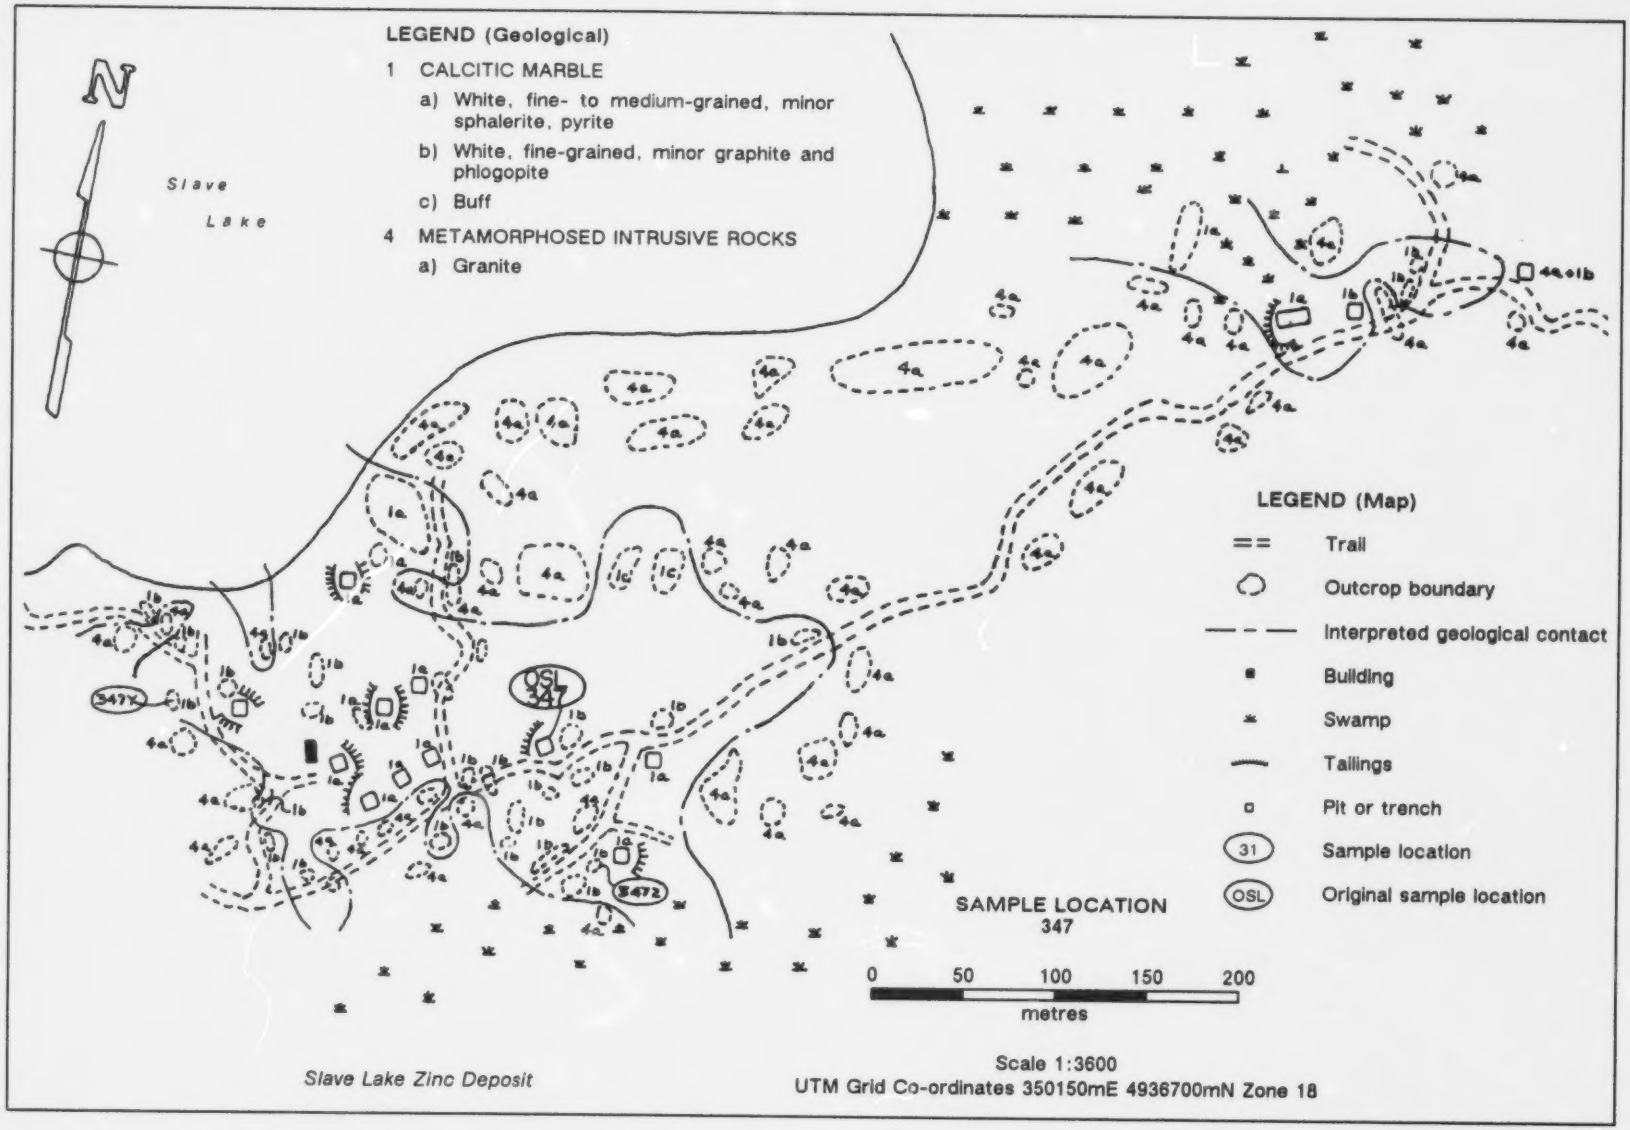

Figure 36. *Location Map, Sample 347.*

MAP AREA 352

Location

Southeast corner of Burleigh Township, approximately 1.5 km west of Petroglyphs Provincial Park.

Map reference: NTS 31D/9; UTM 732510mE, 4941170mN, Zone 17.

Access

Four kilometres west of Stonyridge, on a good paved road. The sample was taken at the bridge crossing Eels Creek.

Regional Geology

This sample comes from a north- to northeast-trending marble belt which is 6 to 8 km wide by tens of kilometres in length. Minor conformable amphibolite beds lie within the marble along with a narrow granitic gneiss unit. The marble is flanked to the west by granitic gneiss, to the east by paragneiss and amphibolite, and to the south by granitic gneiss which is partially overlain by Paleozoic sedimentary rocks.

Local Geology

Detailed mapping of this area (Figure 37) indicates that there are two distinctive marble types. One is grey with light grey laminations, local quartz-feldspar veining, and minor amounts of phlogopite and graphite. The second unit, from which the sample was taken, is white with only minor impurities and a medium grain size. There is a thin unit of granite running adjacent to the white marble band. It is probable that the granitic intrusion caused more complete recrystallization of the white marble. Within the grey marble units are small bands of amphibolite conformable to the marble. Impurities within the marble are mainly biotite, phlogopite, and graphite, usually totalling no more than 5 percent.

Previous Geological Work

Burleigh Township has been mapped by Adams and Barlow (1910), Satterly (1943), and Hewitt and Satterly (1957).

Chemistry

Samples taken from this marble belt (samples 349 to 354 and 1450 to 1454), with the exception of sample 352, tend to have a high SiO_2 contents. CaO/MgO is in the range of 8 to 12 for most of the samples, while trace and metallic element contents are low in all samples.

Potential

Marble in this area is poor in quality, with the exception of the white marble band described above, which is highly calcitic and low in impurities. More work is required in the area to determine the extent and chemical consistency of the white marble band.

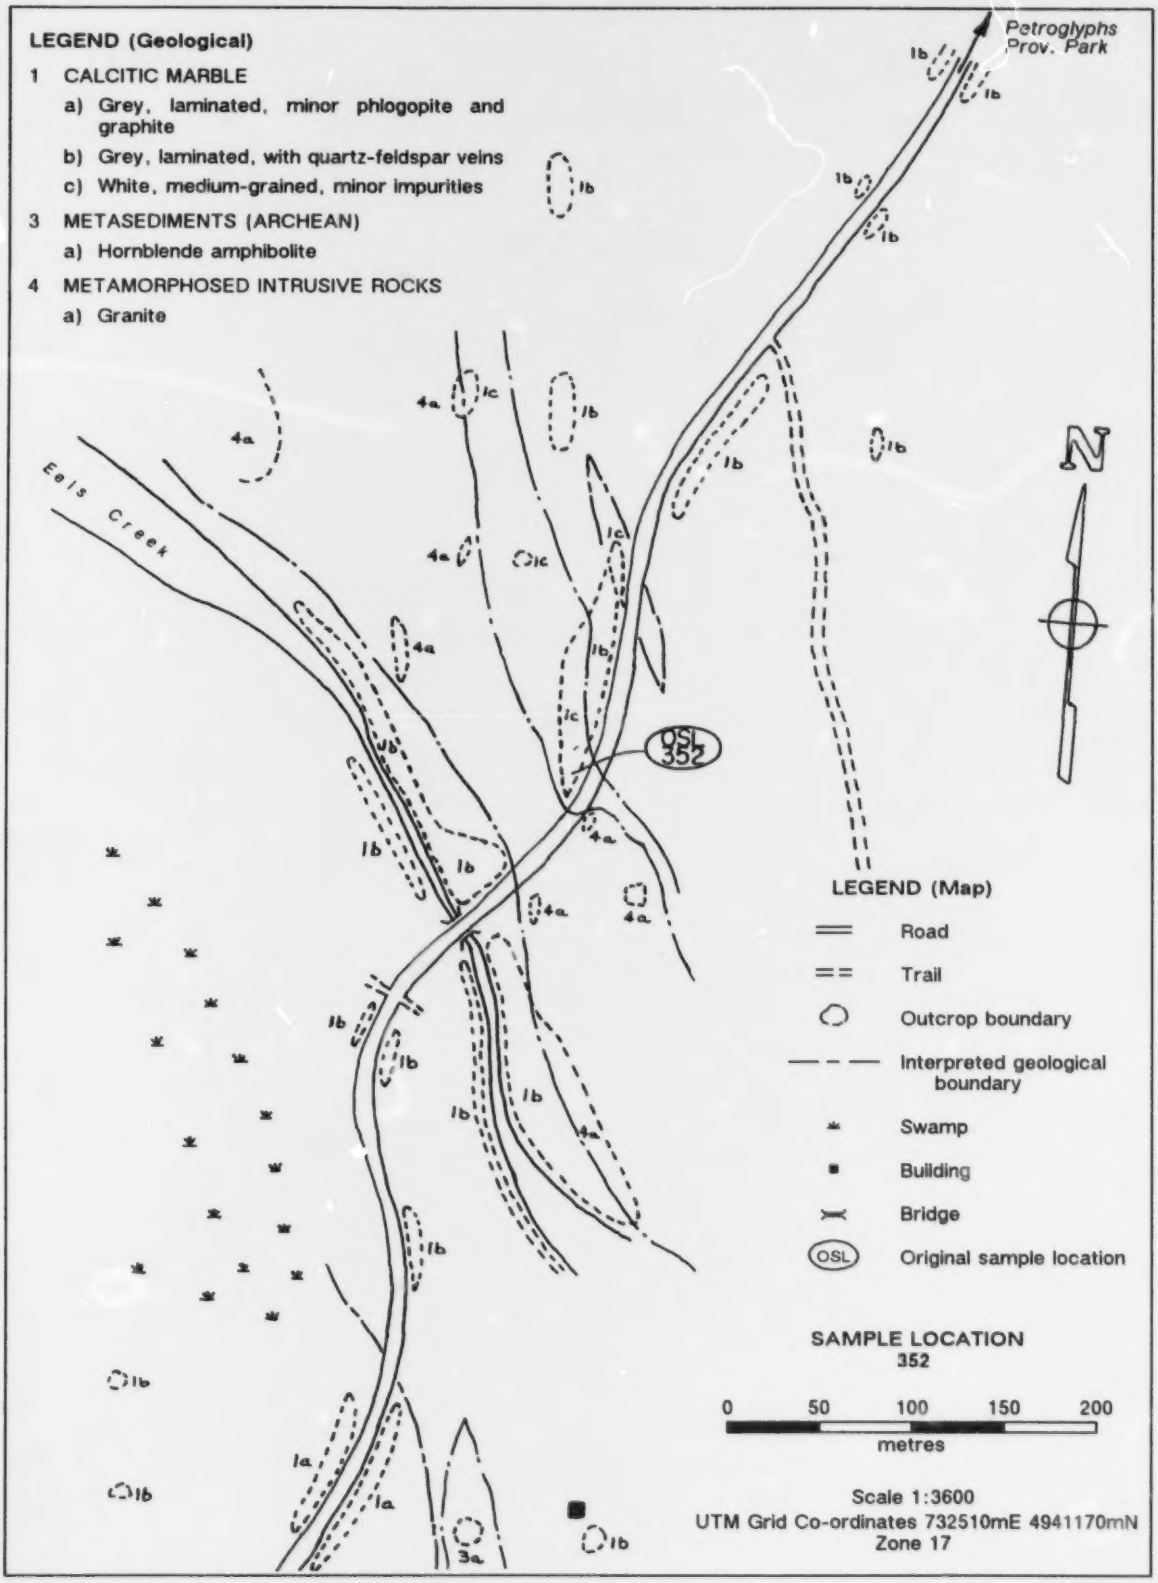

Figure 37. *Location Map, Sample 352.*

MAP AREAS 356 AND 367

Location

Both of the marble samples come from a marble belt in Kennebec Township.

Map reference: NTS 31C/10.

356—UTM 344300mE, 4952250mN, Zone 18.

367—UTM 337650mE, 4947300mN, Zone 18.

Access

356—This sample was taken along the abandoned railway that runs through Arden. It was sampled at the intersection of the railway line with a dead end cottage road, Concession VI, Lot 15.

367—This sample was taken on a rough one-lane trail which runs parallel to Highway 7, through Elm Tree, Concession I, Lot 10.

Regional Geology

Both of these samples come from a northeast-trending marble belt which is part of a much wider metasedimentary belt. Much of the metasedimentary unit has been intruded by granite, which now flanks the metasedimentary belt to the north and south and pinches the metasedimentary belt out at the southwestern edge of the belt. The marble is bounded to the north by metasediments and amphibolite metavolcanics. Within the marble belt are many conformable metasedimentary layers up to a few hundred metres wide and hundreds of metres long.

Local Geology

356—The marble of this detailed map area (Figure 38) is predominantly light grey to white. There is a band of dolomitic marble which runs conformable to the local structural trends. This marble contains considerable silicate material as clots and mafic material which appears to have been rafted from a nearby source during metamorphism. The calcitic marble is interbedded with dolomitic marble and is buff coloured, containing blebs of quartz and disseminated pyrite.

367—The marble in this map area (Figure 39) is dominantly grey with fine laminations of a lighter grey marble. Much of the marble is relatively impurity free, with only minor pyrite and phlogopite. Diopside crystals up to 5 cm in length occur locally. Some of the marble outcrops contain silicate boudins and clots, but these are not confined to any particular horizon.

Previous Geological Work

Kennebec Township has been mapped by Meen and Harding (1942), Hewitt (1964a), and Wolff (1982a).

Chemistry

Most of the marble samples from this marble belt (samples 355 to 367 and 428 to 456) are dolomitic in composition, with the more calcitic material occurring at the northern edge of the belt. Regionally, the closeness of the sample location to a metasedimentary unit tends to influence the amount of silicate material in the sample; samples close to the metasediment-marble contact have a higher impurity content due to the gradational nature of the contact. Trace element and base metal contents in this belt are at or very near to background levels. Channel sampling in these map areas indicates rather uniform compositions. Sample 356z has less than 1 weight percent SiO_2 along with a high CaO content, with 60 percent reflectivity. Each of samples 365x, 365y, and 365z have a low SiO_2 content, a high CaO content, and a reflectivity between 60 percent and 64 percent.

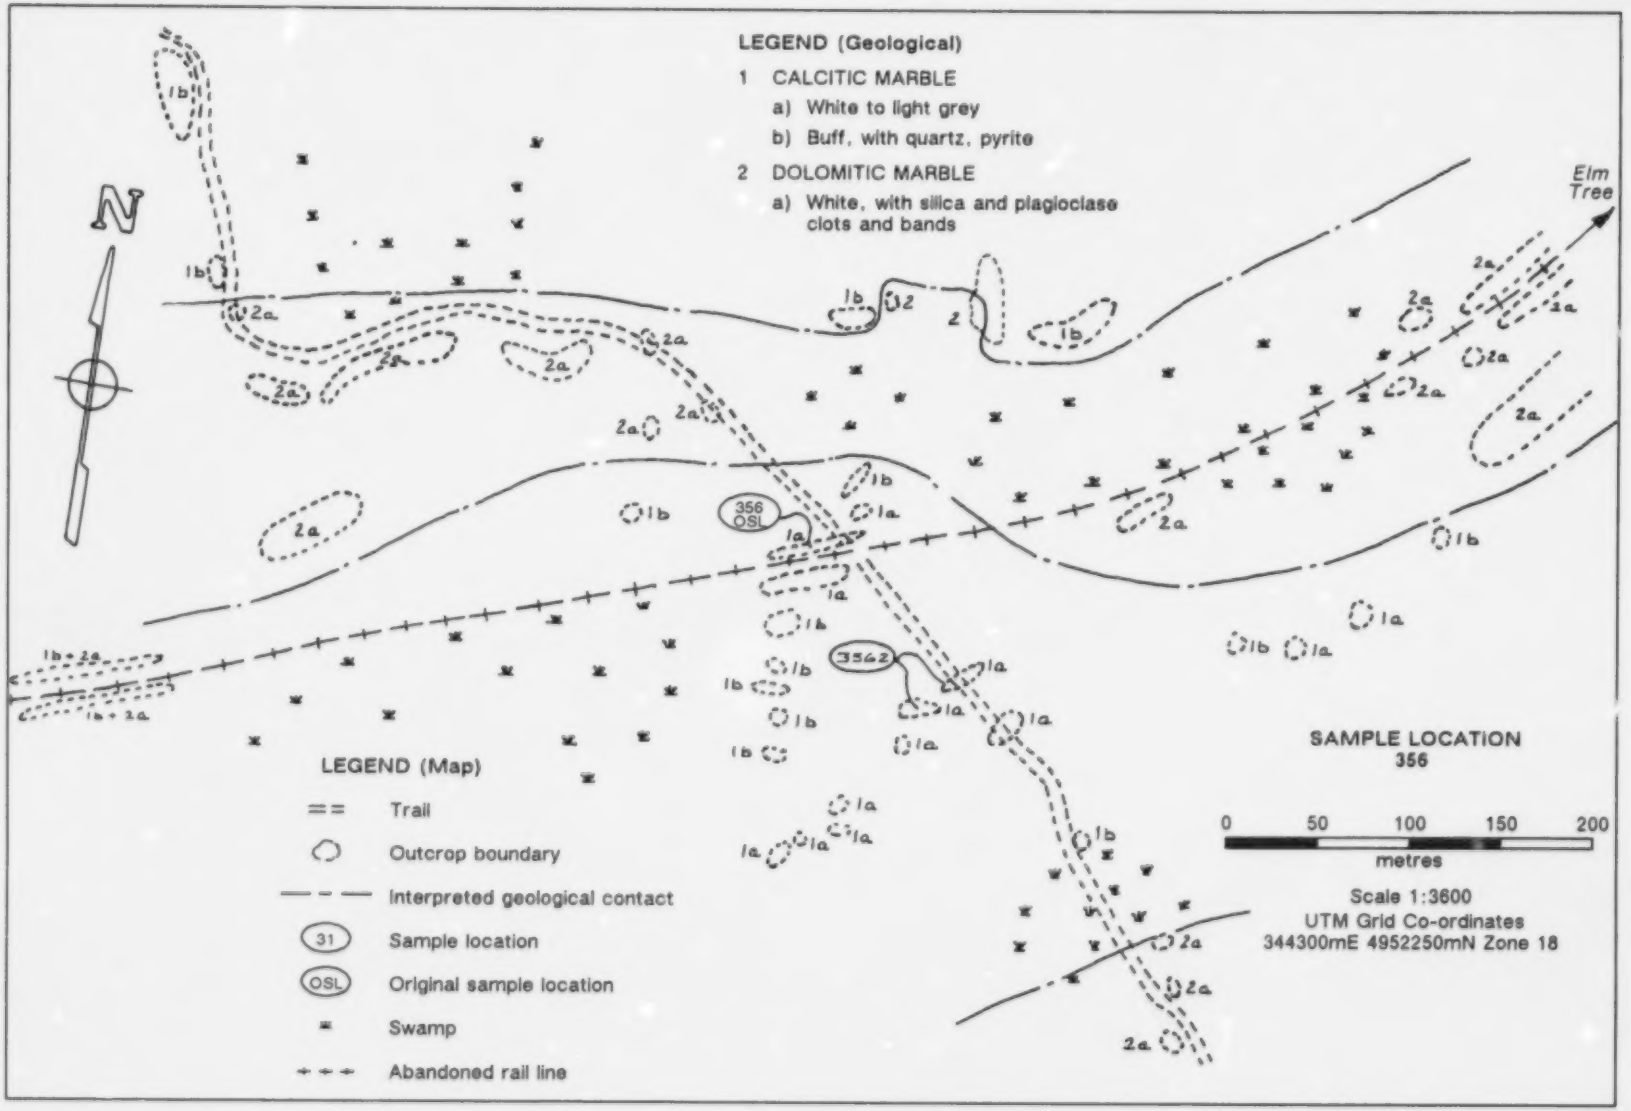

Figure 38. *Location Map, Sample 356.*

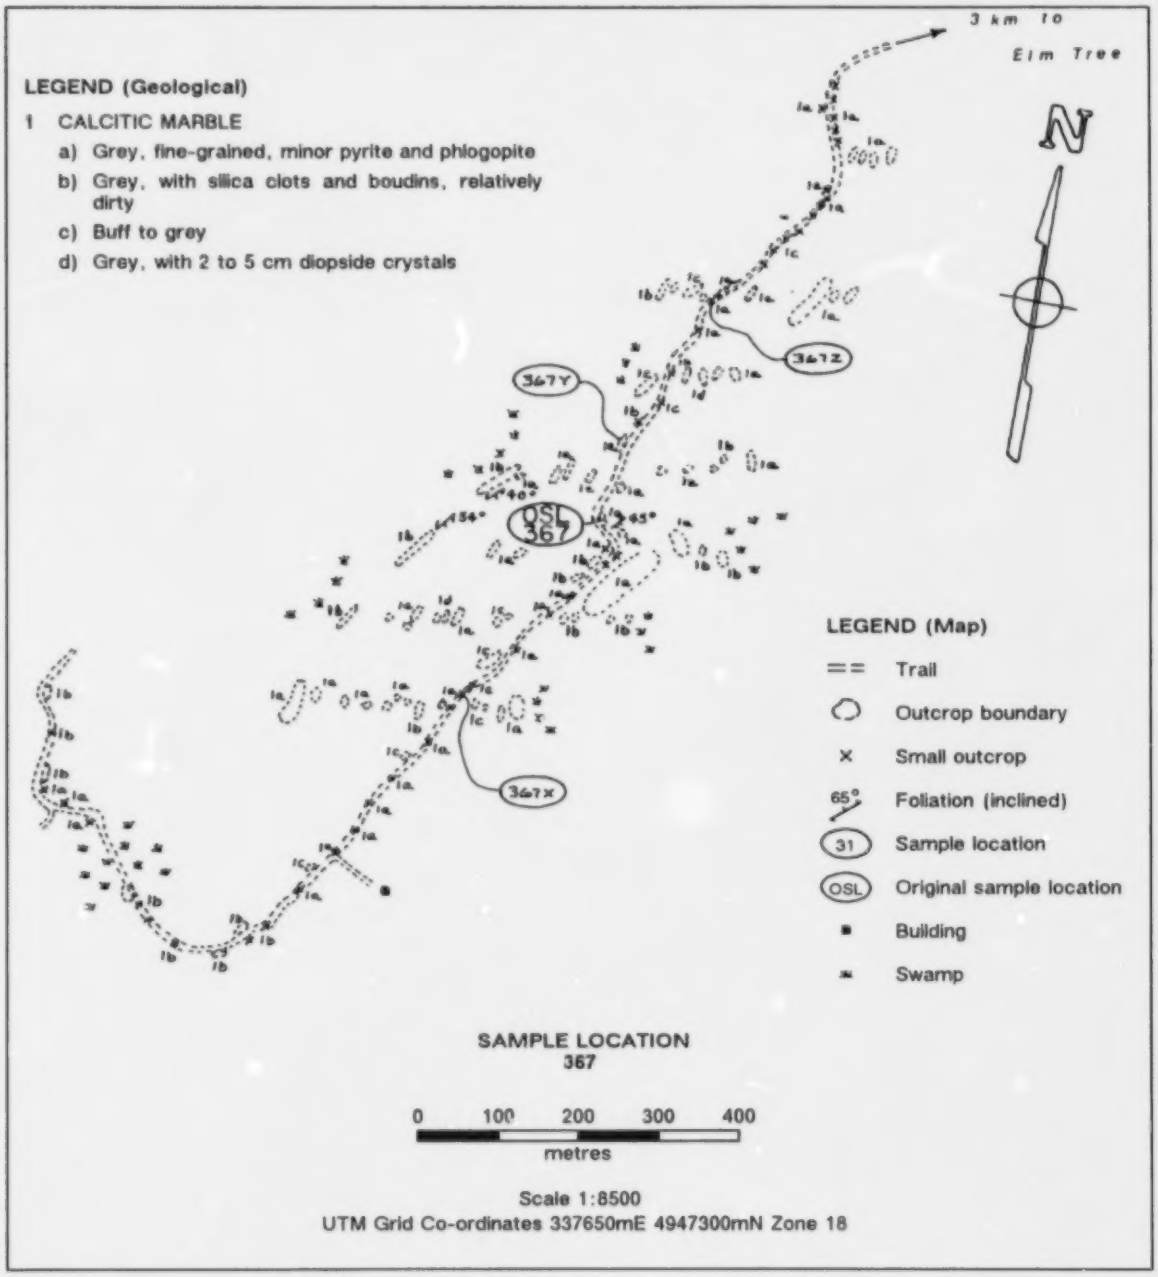

Figure 39. *Location Map, Sample 367.*

MAP AREA 424/425/426/427

Location

The Bonter Marble Quarry, east-central Marmora Township.

Map reference: NTS 31C/12; UTM 293400mE, approximately 4936600mN, Zone 18.

Access

Turn east on the one-lane road at Malone, situated 1 km southeast of Malone, Concession XI, Lot 16.

Regional Geology

All samples were taken from the Bonter Marble Quarry near Malone. This quarry is situated within a narrow marble belt trending approximately N30°E. In the past, marble from this quarry was used for terrazzo chips, poultry grit, and in the pulp and paper processing industry. The marble is bounded by granite gneiss, with minor amounts of diorite on both sides.

Local Geology

Marble within the detailed map area is generally white with variable amounts of phlogopite, graphite, and minor silicate minerals (Figure 40). Grey bands and streaks within the marble are concentrations of graphite. In the quarry from which sample 425 was taken, there is a 2 cm wide band of long-fibered asbestos, which has a woody appearance. In the quarry from which sample 426 was taken, there are several mafic veins crosscutting the marble, some of which are incompletely boudined (Photo 4). Magnetite occurs in both massive and banded forms in a test pit slightly east of the northernmost quarry. In other zones there are hematite-stained patches, siliceous pyrite-rich bands, and marbles containing clots of silicate material. The contact between the metamorphosed intrusive granite and diorite, and the marble is generally very well defined and sharp, with only minor silicate contamination of the marble.

Previous Geological Work

Marmora Township has been mapped by Wilson (1940b) and Hewitt and Satterly (1957).

Chemistry

Only one of the four samples taken at this quarry had more than 0.43 weight percent SiO_2. The other three samples have very high CaO and low MgO contents. The fourth sample, sample 425, has almost 10 weight percent SiO_2 along with a high CaO content. Trace and metallic element contents are low in all four samples.

Potential

It may be assumed that the best material has been removed from this area, but mapping reveals that there is still a considerable quantity of high-calcium marble in the quarry area. It is very likely that other, very similar marble zones exist within the immediate area as well as in western Madoc Township.

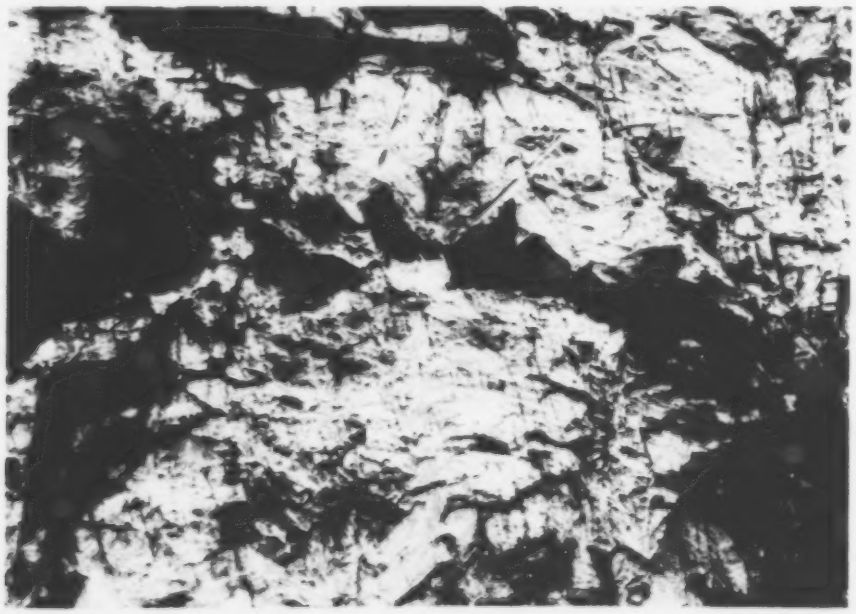

Photo 4. *Deformed mafic dike in grey streaked white marble, in map area 424/425/426/427.*

Access

480—5 km south of Clarendon Station, Highway 509, Concession II, Lot 24.

489—On a one-lane farm road, 1 km north of the main gravel road, Concession V, Lot 23.

497/498/499—On the main gravel road, 3 km north of Silver Lake.

497—Concession VI, Lot 24.

498—Concession VI, Lot 24.

499—Concession VII, Lot 24.

Regional Geology

All of the samples come from a generally north-northeast-trending metasedimentary-marble belt with an irregular shape caused by the intrusion of igneous rocks. The igneous rocks range in composition from granite to diorite. Throughout the area there are numerous metasedimentary units, some of which are continuous across several hundred metres, while others are only a few metres in length. Metasedimentary rock types include paragneiss, hornblende amphibolite, and chlorite-biotite schist. Calcitic marble in the belt is predominantly light grey with a relatively uniform composition and structure. Dolomitic marble occurs as discrete bands within the calcitic marble but is insignificant in quantity.

Local Geology

480—Marble within the detailed map area is generally light grey with minor disseminated phlogopite and pyrite (Figure 41). This material grades into contaminated marble containing minor quartz and mica, and finally into an interbedded grey marble and amphibolite. Individual metasedimentary units are up to 100 m in surface width.

489—Road outcrops in this map area (Figure 42) indicate that the marble is uniform in composition with only minor metasediments occurring at the north end of the map area. Impurities within the marble are only minor with a gradation to slightly more silica-rich material in certain bands. Laminations are from 1 to 3 cm in thickness across all of the marble units.

497/498/499—This part of the marble belt (Figure 43) is largely uniform in appearance and composition. "Clean" marble contains only minor phlogopite, while "impure" marble contains several percent silica, biotite, plus calc-silicate minerals as clots and boudins. Dolomitic marble is similar in appearance to calcitic marble. Small discontinuous bands of metasediments occur within the marble. The marble in this area is virtually identical to the marble in map areas 480 and 489.

Previous Geological Work

Oso Township has been mapped by Harding (1951) and Hewitt (1964a).

Chemistry

The majority of samples from this marble belt (samples 474 to 500) are calcitic and rarely contain more than 3 percent SiO_2. There are several dolomitic samples located at the southern side of the belt. Trace and metallic element contents are low throughout this belt.

Detailed channel sampling in map area 497/498/499 reveals that this area has a uniformly low SiO_2 content and a high CaO content. Reflectance in these samples ranges from 60 to 70 percent.

Potential

Most of the marble in this belt contains nearly 5 weight percent MgO, but only minor amounts of other contaminant elements. The light grey colour is persistent across strike as is the marble purity, but the calc-silicate clots and boudins which are scattered throughout the detailed map areas may raise the average total impurity content of the marble.

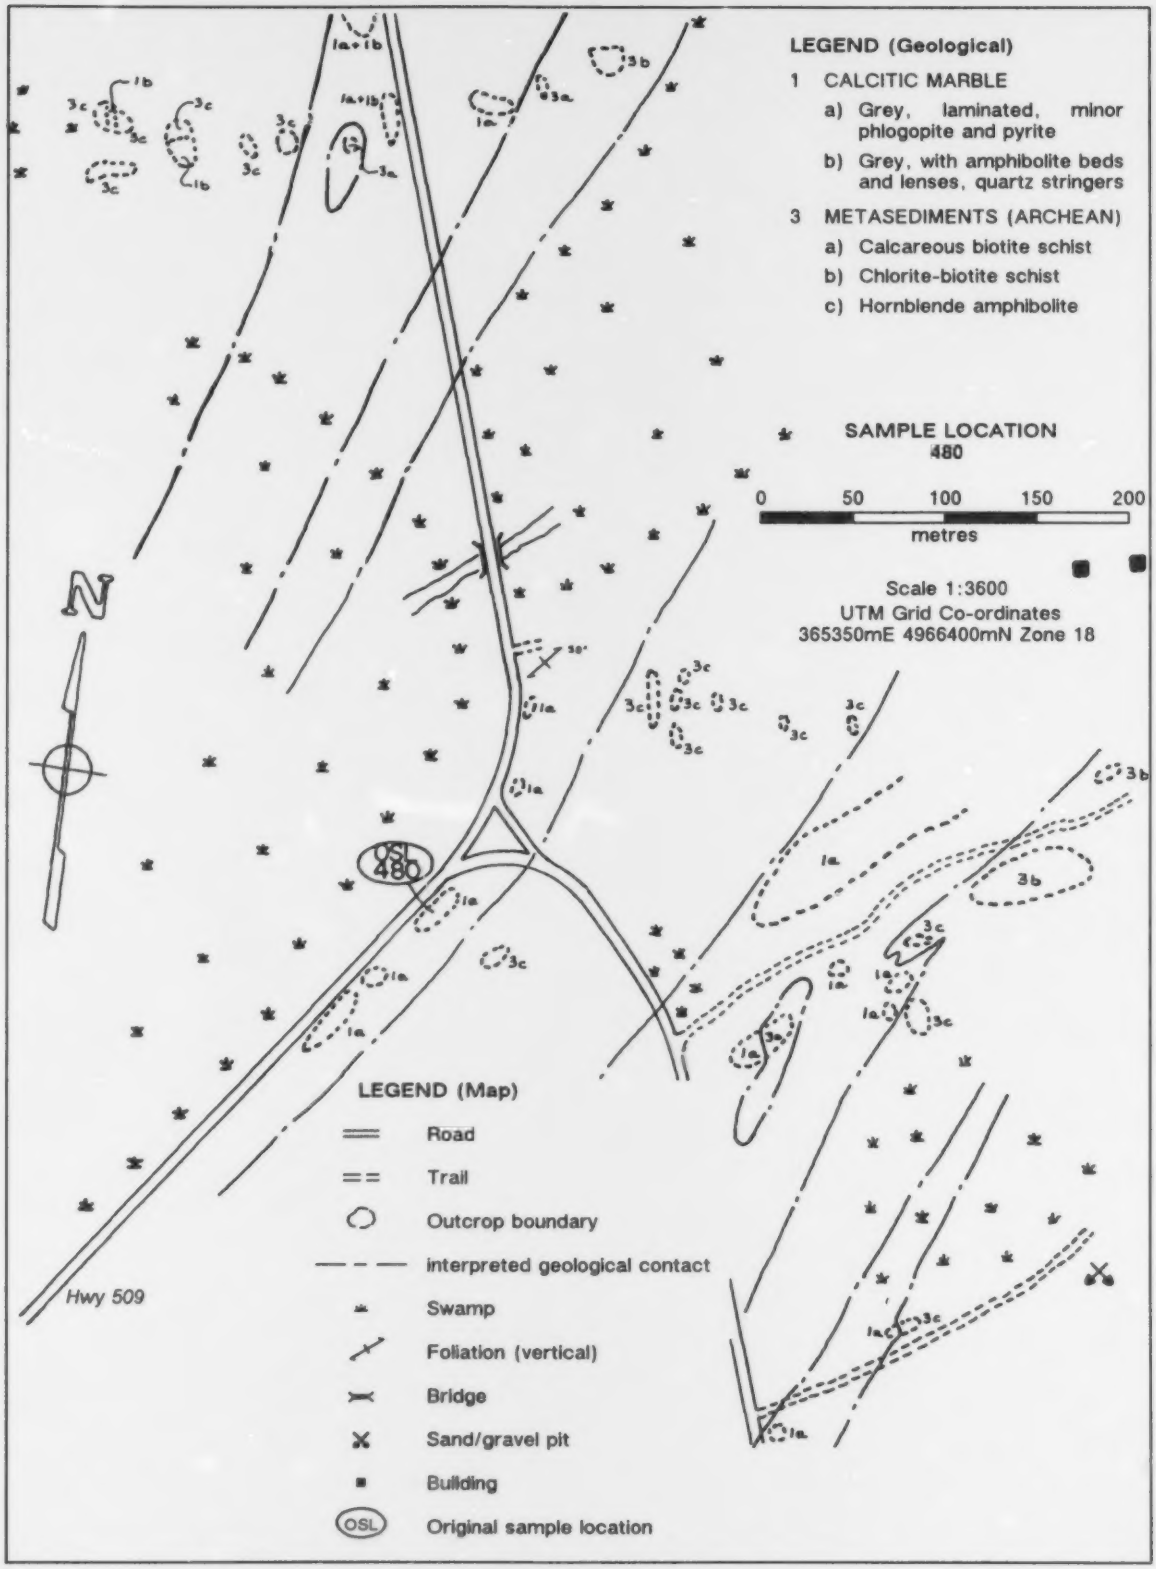

Figure 41. *Location Map, Sample 480.*

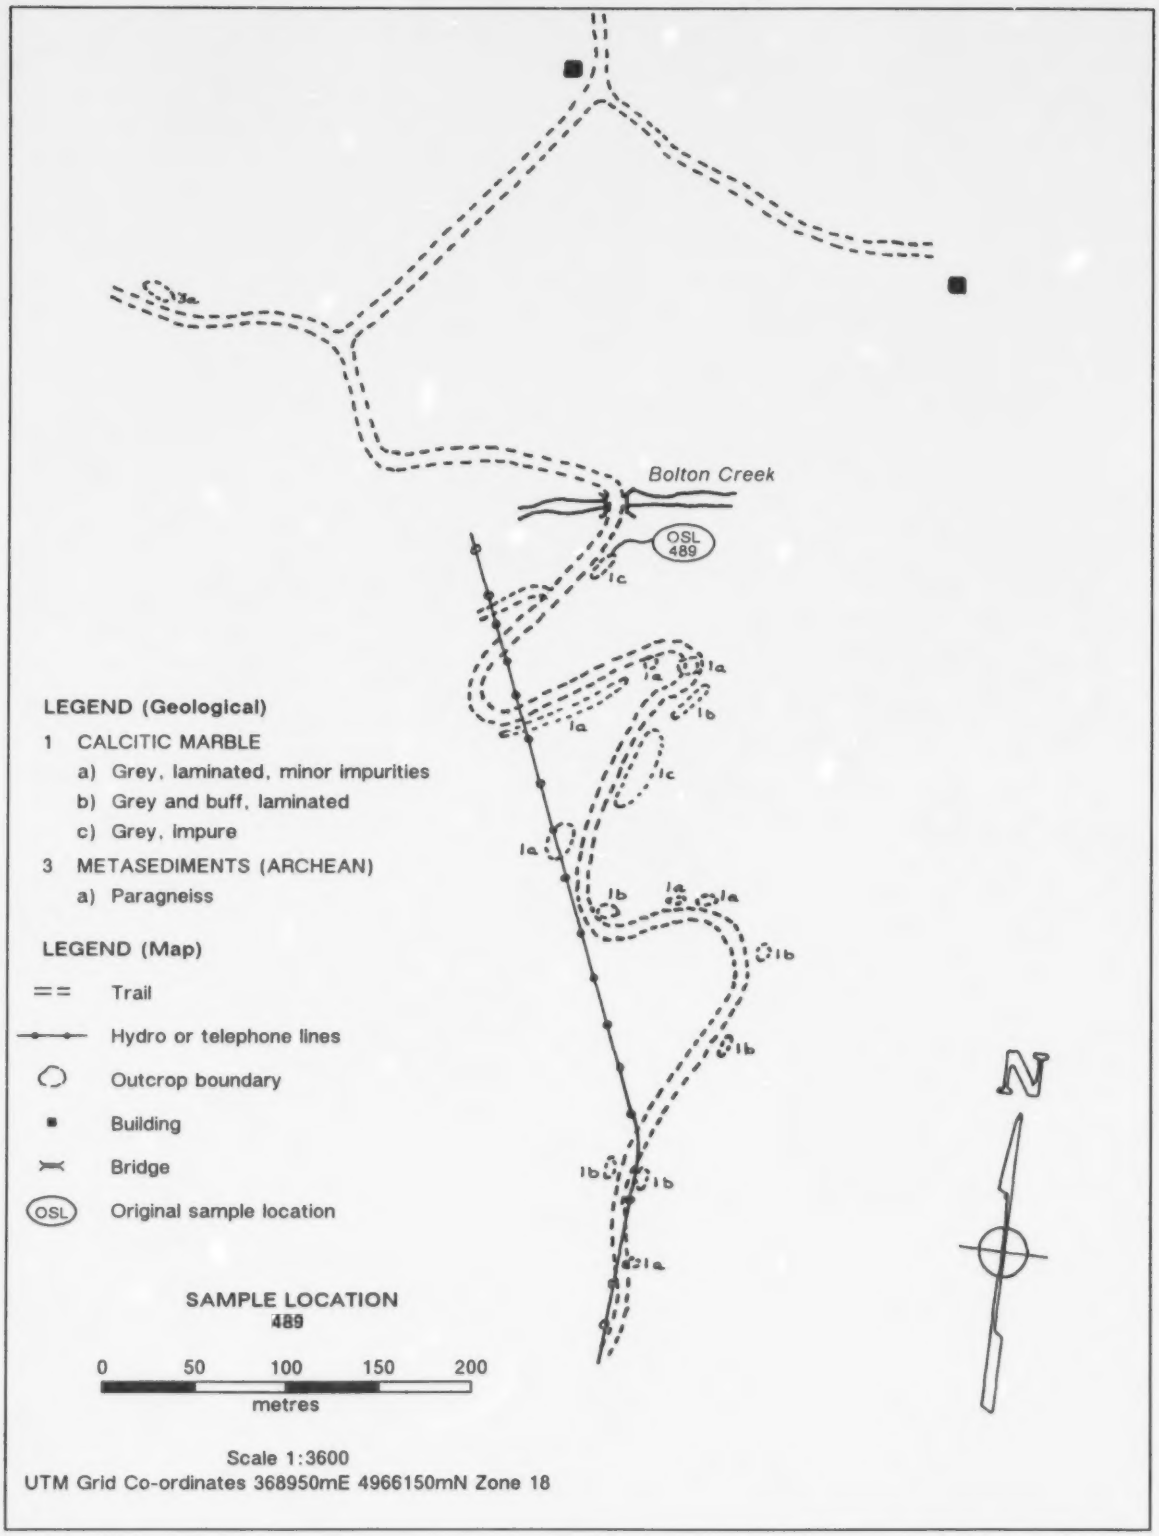

Figure 42. *Location Map, Sample 489.*

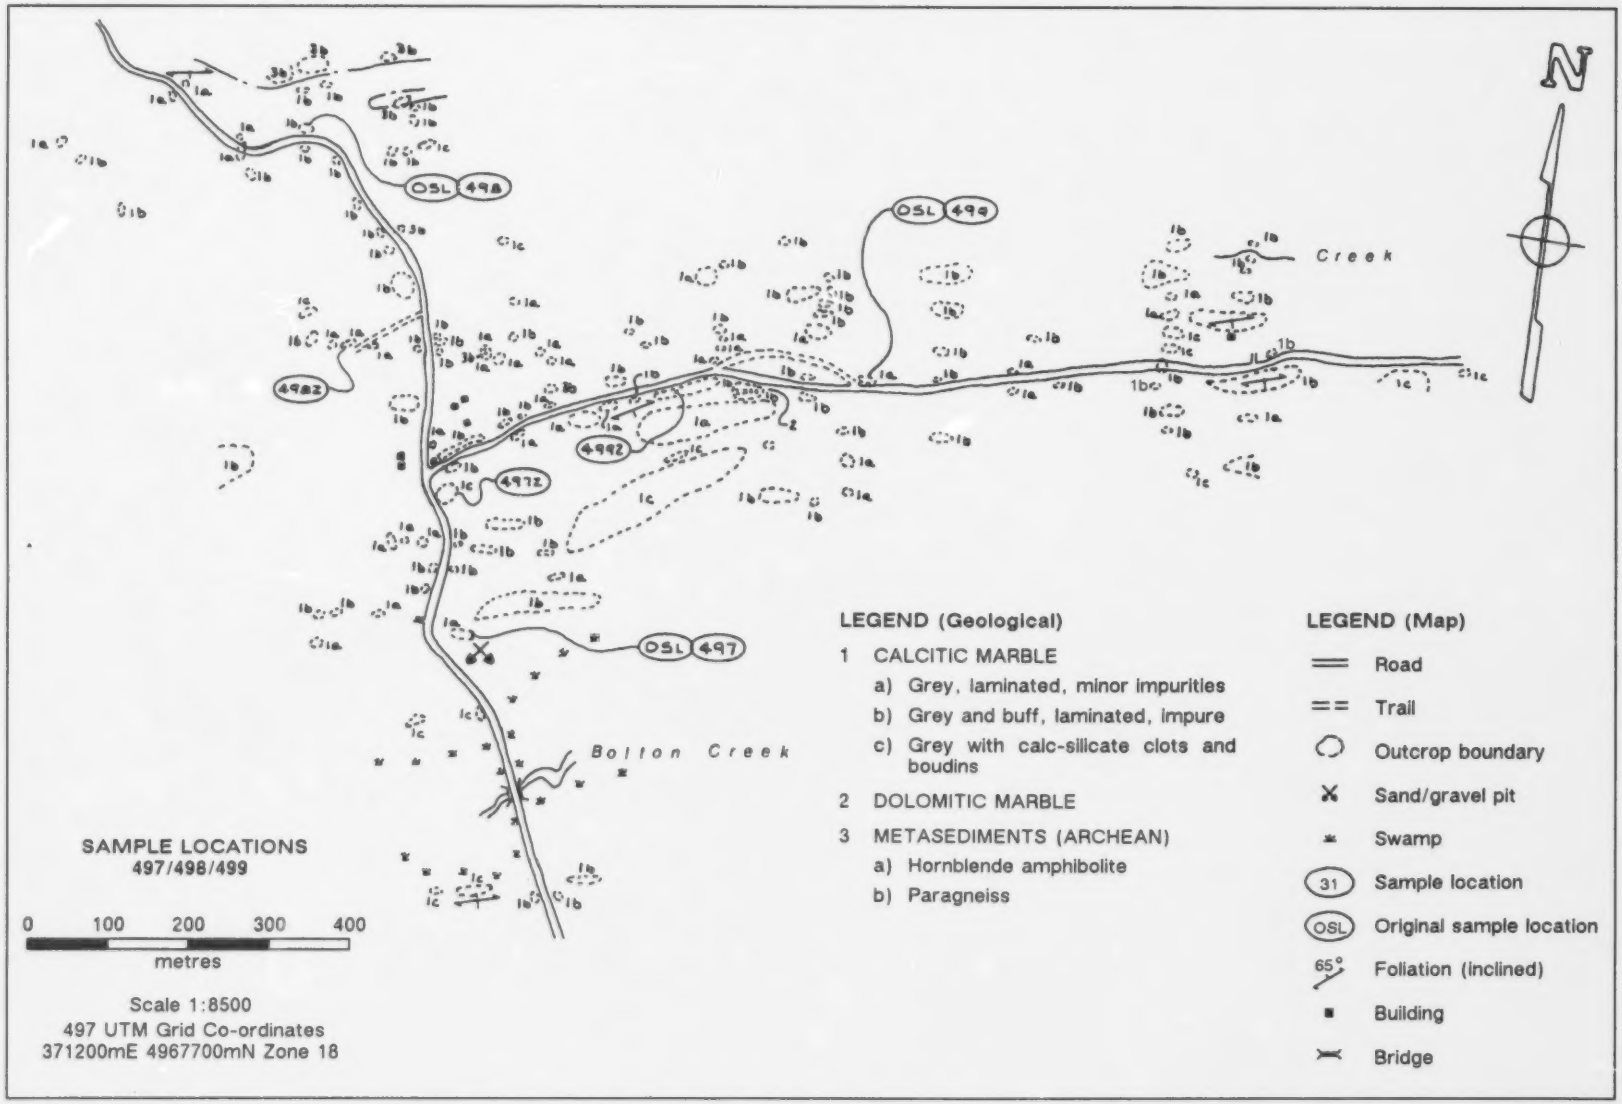

Figure 43. *Location Map, Samples 497, 498, and 499.*

MAP AREA 483

Location

Olden Township.

Map reference: NTS 31C/15; UTM 357800mE, 4957450mN, Zone 18.

Access

On Highway 7, 5 km east of the Mountain Grove turnoff, Concession V, Lot 16.

Regional Geology

This sample was taken from a linear marble belt which runs east-northeast in the vicinity of Sharbot Lake. The belt is conformable with metasediments and metavolcanics. These conformable rock units are intruded throughout by small granitic bodies.

Local Geology

Detailed mapping at this sample location (Figure 44) delineates a fine-grained laminated grey marble interbedded with fine-grained wacke. Impurities within the marble include fine-grained pyrite and phlogopite, with zones of narrow quartz veining. Contacts with the wacke tend locally to be gradational, with calcareous sedimentary rocks at the contacts.

Previous Geological Work

Olden Township has been mapped by Harding (1951), Hewitt (1964a), and Wolff (1982b).

Chemistry

Regional samples within this marble belt (samples 451, 452, 457 to 470, and 483) are generally calcitic in composition with only minor occurrences of dolomitic marble. Trace and metallic element contents are low throughout the belt. One channel sample from the detailed map area shows a low SiO_2 content along with a high CaO content. Reflectivity is low at 53 percent, which is expected since the marble is consistently grey.

Potential

The marble immediately around the detailed sample site is unfavorable as filler material due to its grey colour. The marble belt widens along strike and it is possible that more favorable material exists farther along the belt.

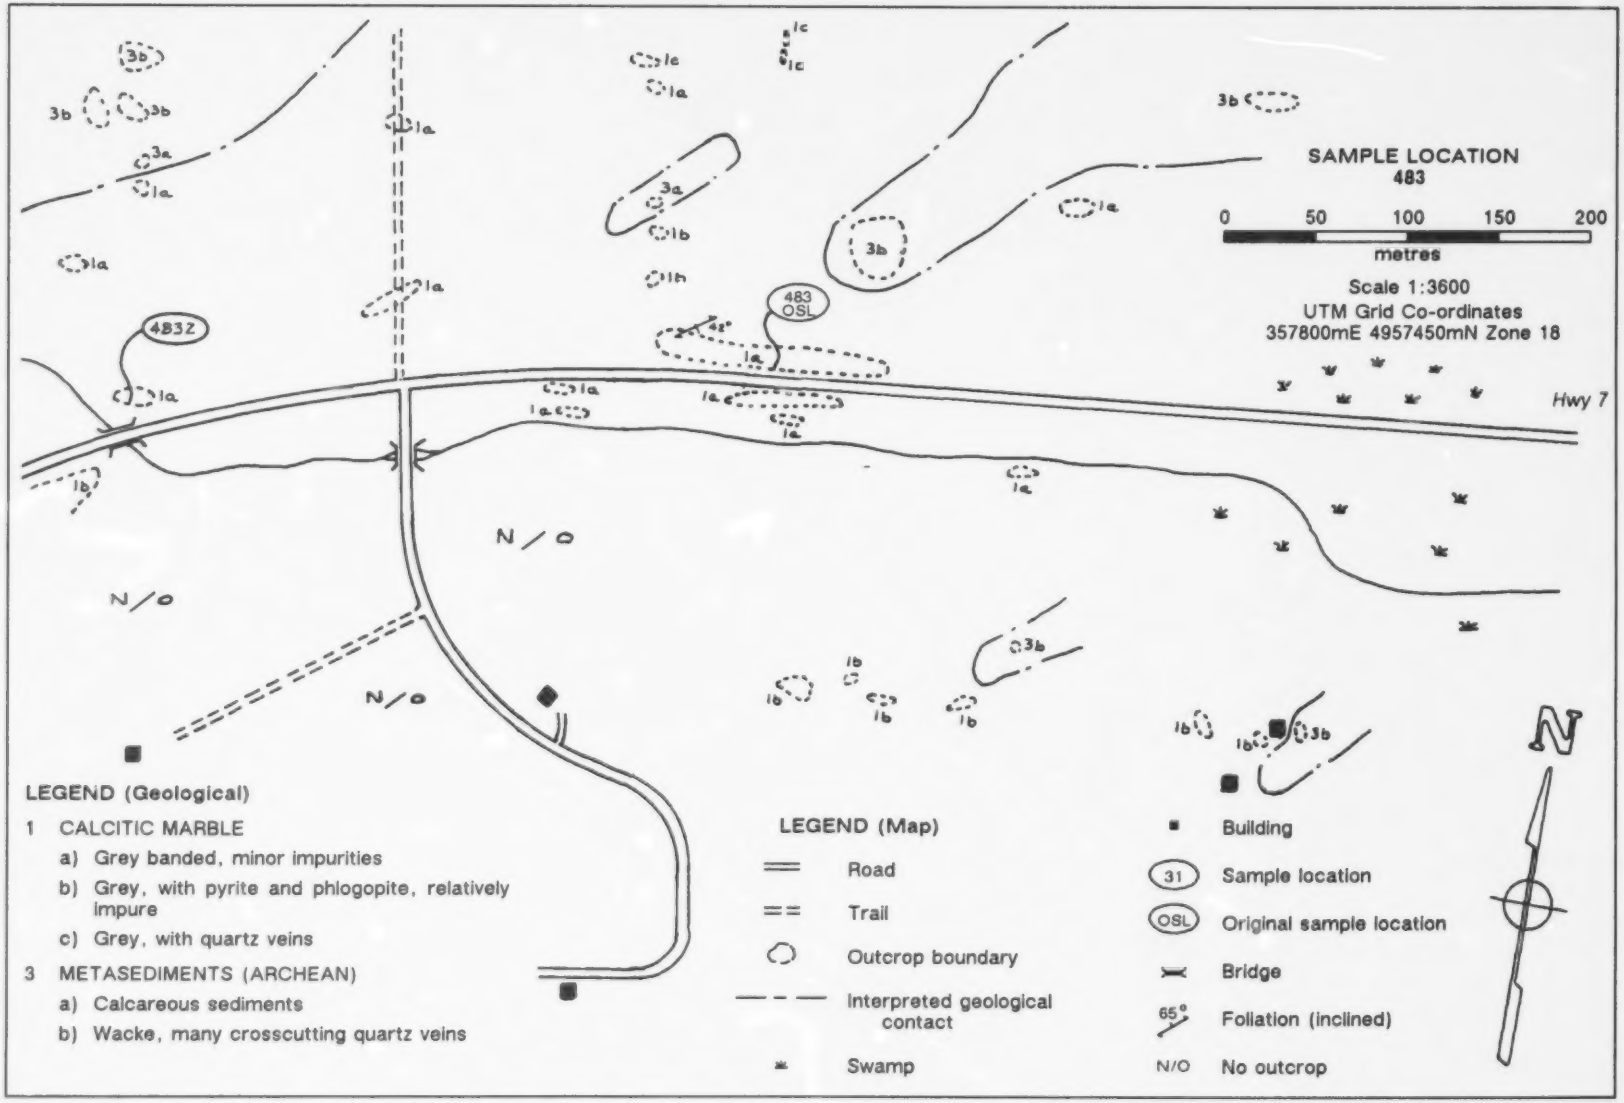

Figure 44. *Location Map, Sample 483.*

MAP AREAS 516 AND 710/711/731/733

Location

516—South of Actinolite, Elzevir Township.

711—Elzevir Township.

Map reference: NTS 31C/11.

516—UTM 314950mE, 4934200mN, Zone 18.

711—UTM 317950mE, 4936200mN, Zone 18.

Access

516—A few hundred metres south of Actinolite on Highway 37, Concession IV, Lot 1.

711—From a small marble quarry on the north side of Highway 7, approximately 3 km east of the Highway 37–Highway 7 intersection, Concession VII, Lot 2.

Regional Geology

These samples were taken from a thin marble belt which runs through Actinolite toward Kaladar. The belt is bounded by granite and paragneiss to the north and south and in part by metavolcanics which pinch out just north of the original sample location for sample 710. Minor metasediments and metavolcanics lie conformably within the white medium- to coarse-grained calcitic marble.

Local Geology

516—This portion of the marble belt is 150 to 200 m wide on the surface and is bounded on both sides by metasediments (Figure 45). The marble is white and fine to medium grained, with only minor amounts of disseminated phlogopite and graphite. To the south of this area are two former marble workings held by Vermont Marble:

1. Fardom Marble Quarry, which shipped marble blocks and building stone, is located on the west side of Skootamatta River, 1 km south of Actinolite.
2. The second location of marble workings is located 2 km south of Actinolite on the east side of the river.

At each of these locations, white marble with minor impurities is found. At the Fardom Quarry, mafic blocks and bands locally disrupt the marble horizon.

711—This area (Figure 46) was mapped on a regional scale to show the large area of good calcitic marble potential. The mineral rights to much of this area are held at present by Vermont Marble. Metasediments make up the northern boundary of the marble belt while the southern boundary is metamorphosed granite. Just south of Highway 7 at the eastern edge of the map is an old marble showing with two test sample locations from previous exploration. The marble belt tends to get wider east of this location, where a small zone of blue marble is seen.

Previous Geological Work

Elzevir Township has been mapped by Wilson (1940a), Meen and Harding (1942), and Hewitt (1964a).

Chemistry

Most of the samples taken from this belt (samples 515 to 518 and 710 to 716) have high CaO contents (greater than 54 weight percent), with less than 2 weight percent SiO_2. There are also several conformable dolomitic marble bands within the belt which are also white and are relatively free of impurities. Most of the samples have low trace and metallic element contents with the exception of sample 710, which contains anomalous quantities of lead and zinc (113 ppm Pb, 810 ppm Zn).

Potential

The history of work in this marble belt and the widespread occurrence of white clean marble indicates that this entire belt has a high potential for industrial filler-type marble. Vermont Marble has two holdings in the area; one is 2 km south of Actinolite, and the other is 1.5 km east of the Highway 37 turnoff along Highway 7.

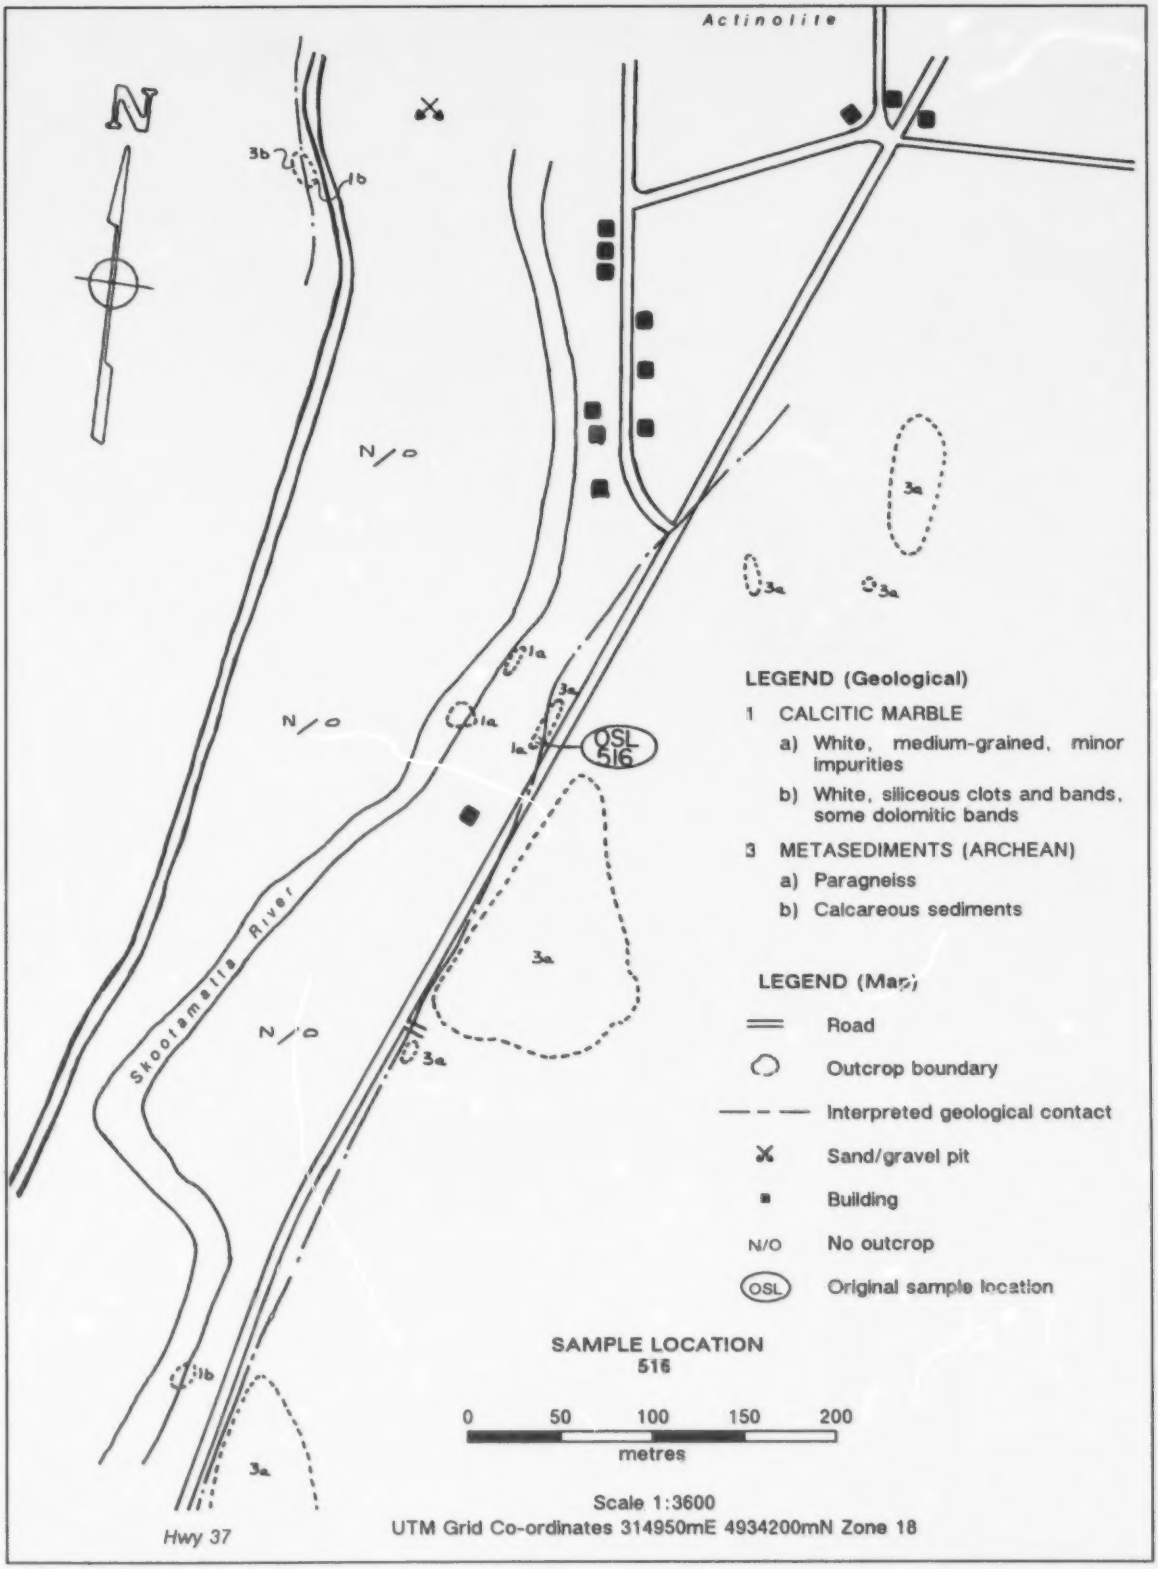

Figure 45. *Location Map, Sample 516.*

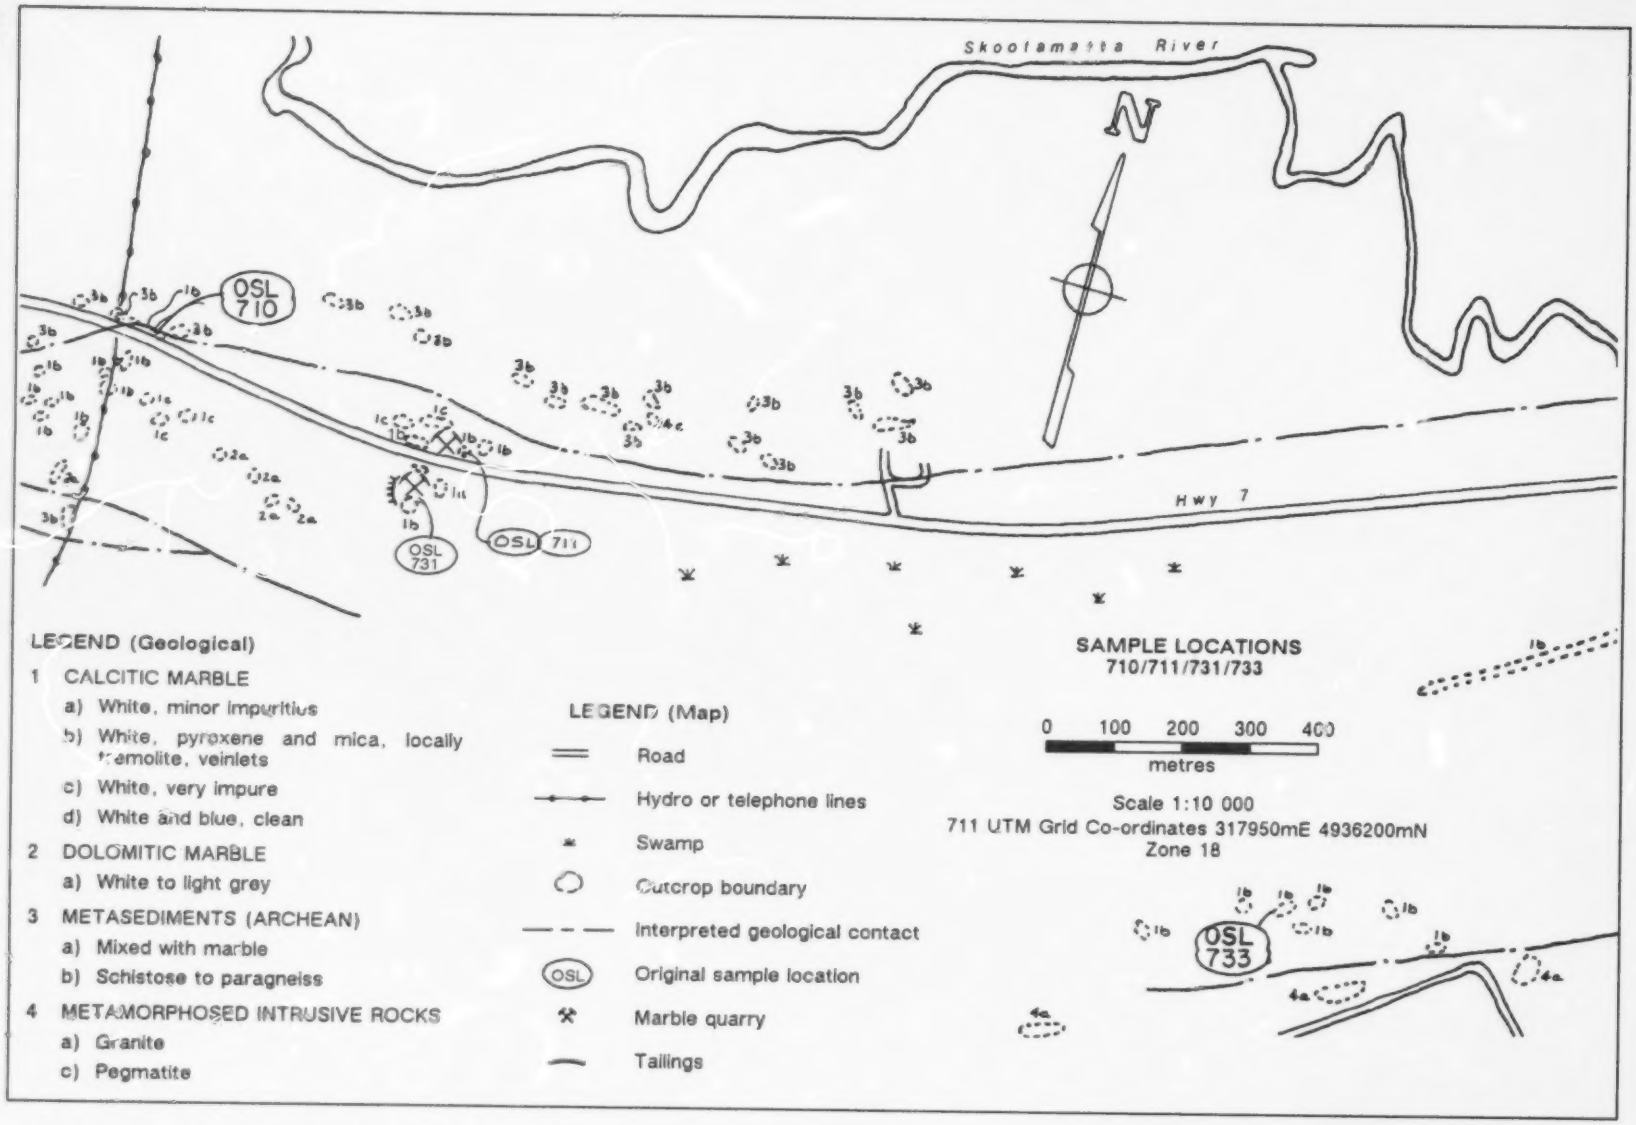

Figure 46. *Location Map, Samples 710, 711, 731, and 733.*

MAP AREA 566

Location

At the east bank of Malcolm Lake, Clarendon Township.

Map reference: NTS 31C/15; UTM 351400mE, 4975350mN, Zone 18.

Access

This sample was taken on the west side of Highway 506, at Malcolm Lake.

Regional Geology

This sample was taken from a northeast-trending marble belt which is located at Malcolm Lake. This belt ranges in width from 1 to 1.5 km, and is bounded on both sides by metavolcanics (Pauk 1982, 1987).

Local Geology

The marble in this area is white to grey with minor graphite, phlogopite, quartz, and plagioclase as accessory minerals. The detailed map area (Figure 47) covers a zone of grey laminated marble which contains inclusions of calc-silicate material and conformable interbeds of metasediments.

Previous Geological Work

Clarendon Township has been mapped by Smith (1958), Hewitt (1964a), and Pauk (1982, 1987).

Chemistry

Most of the samples taken from this marble belt (samples 566 to 580 and 661 to 664) contain relatively high contents of Al_2O_3 and SiO_2. Dolomitic marble samples from this belt also contain high amounts of impurities. Trace and metallic element contents are at or below background levels for marble.

Potential

Marble in the sample area is relatively impure, with high SiO_2 and Al_2O_3 contents. It is unlikely that this material could be used as an industrial filler, although it is very possible that other areas within this belt are less impure.

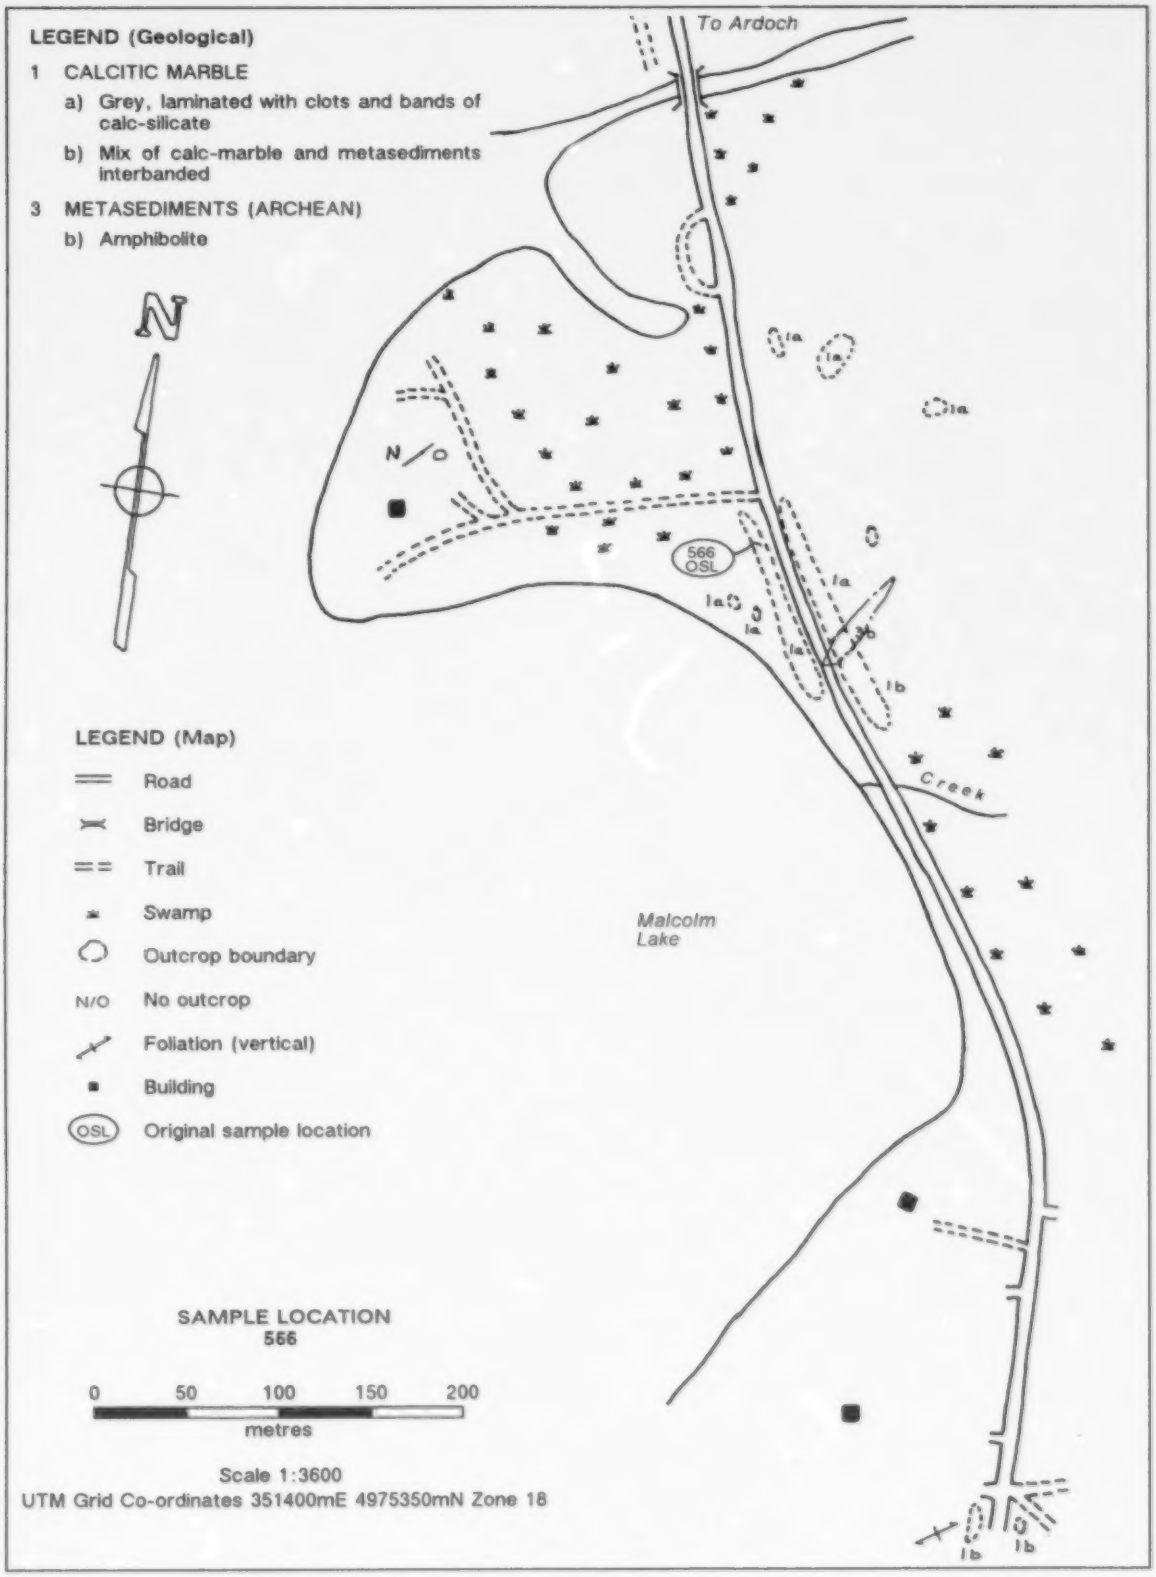

Figure 47. *Location Map, Sample 566.*

MAP AREAS 586 AND 588

Location

Oso Township.

Map reference: NTS 31C/10.

586—UTM 366300mE, 4956300mN, Zone 18.

588—UTM 367000mE, 4953900mN, Zone 18.

Access

586—On Highway 38, 3 km south of Sharbot Lake, Concession I, Lot 9.

588—On Highway 38, halfway down St. Georges Lake, Concession I, Lot 5.

Regional Geology

These samples were taken from small marble units contained within metamorphosed granitic intrusive rocks. The marbles are generally coarse grained and white, with minor disseminated graphite.

Local Geology

586—Marble occurrences in the detailed map area consist of several small marble zones which tend to be discontinuous (Figure 48). The purest marble is white and contains minor serpentine and phlogopite. There are also small units of coarse-grained white marble containing clots of quartz and feldspar. Orange marble is found near the contacts with metamorphosed intrusive rocks, and is usually associated with a high serpentine content (several percent).

588—This sample was taken from a marble belt running parallel to St. Georges Lake (Figure 49). The marble is bounded to the east by metamorphosed intrusive rocks of anorthositic to dioritic composition. The marble is predominantly white, with a medium to coarse grain size. Much of the marble contains disseminated phlogopite and graphite. The more impure marbles contain up to 0.5 m diameter clots of serpentine-rich material, which lends an orange hue to the marble.

Previous Geological Work

Oso Township has been mapped by Harding (1951) and Hewitt (1964a).

Chemistry

Marble composition varies from calcitic to dolomitic, and the silica contents of the different marble zones (samples 586 to 589, 701, 702, and 720, range from less than 1 percent to greater than 10 percent. The dominant marble type is calcitic marble, with up to 8 percent MgO and low SiO_2. Trace and metallic element contents are low throughout the area. The one channel sample from this map area, sample 588z, yields 5 percent SiO_2 with a low reflectivity (59 percent) due to the impurities.

Potential

The relatively large percentage of silicate minerals and other impurities makes this marble an unlikely source for filler material. It is possible that other marble zones contained within the metamorphosed intrusive rocks have lower impurity contents, and if so, the whiteness of the marble would be ideal.

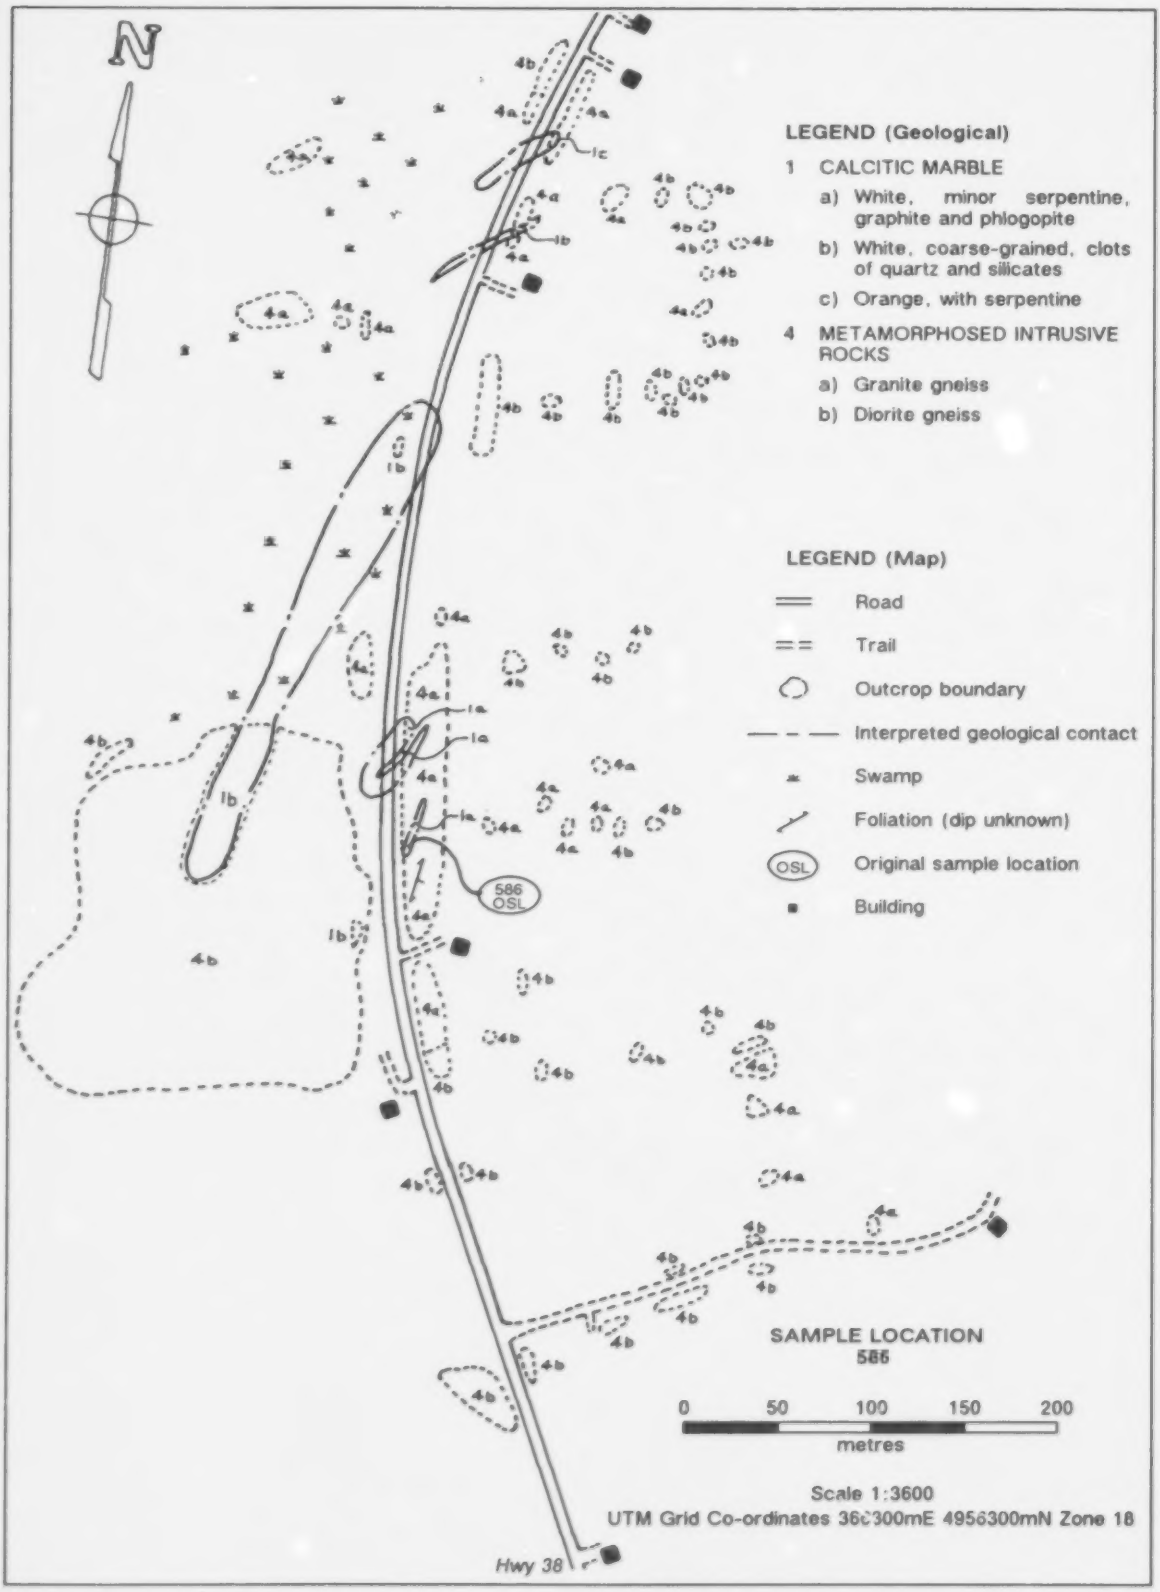

Figure 48. *Location Map, Sample 586.*

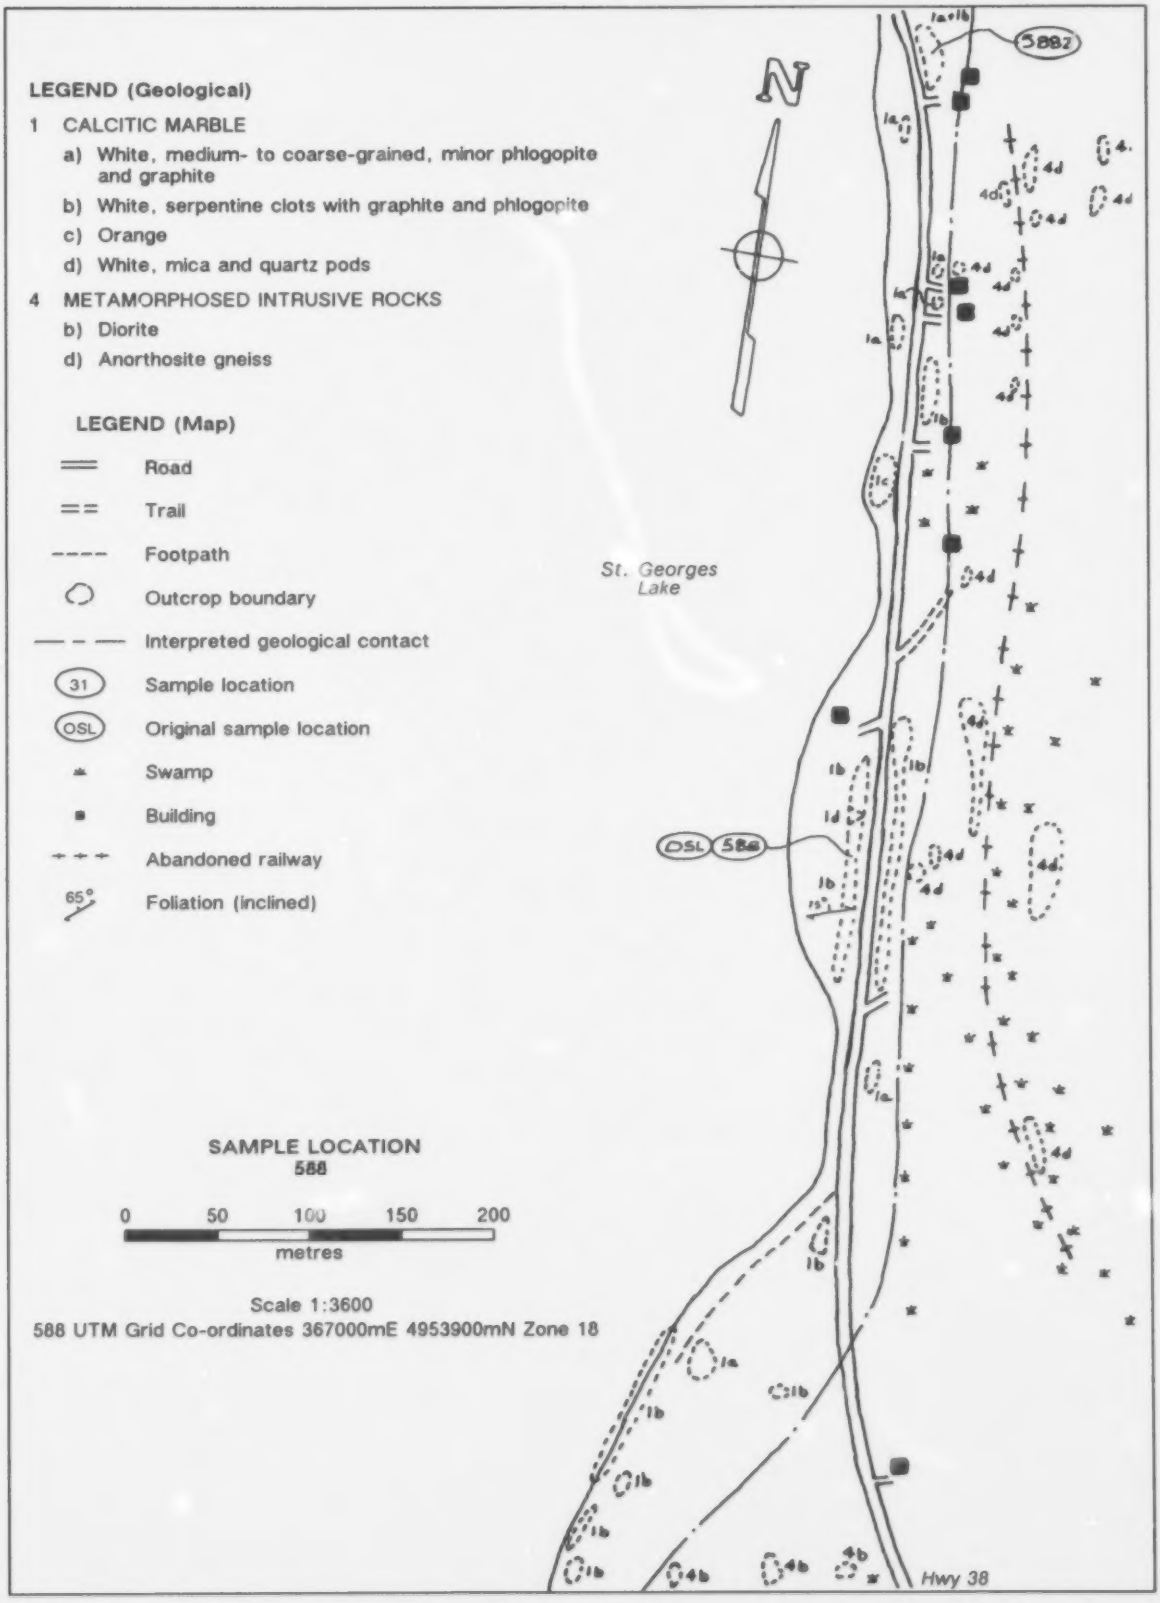

Figure 49. *Location Map, Sample 588.*

MAP AREAS 689 AND 692

Location

Both samples are within the same marble belt on the west side of the Mountain Grove Intrusion, Olden Township.

Map reference: NTS 31C/10.

689—UTM 356200mE, 4952550mN, Zone 18.

692—UTM 355600mE, 4950800mN, Zone 18.

Access

689—On a paved road, 4 km south of Mountain Grove, Concession III, Lot 6.

692—On a gravel road running west from the paved road, Concession III, Lot 6.

Regional Geology

This marble belt is in contact with the Mountain Grove Intrusion to the north, east, and south. The original texture and grain size of the marble has been modified by this dioritic intrusion, as exemplified for example by the trend of the foliation, which is parallel to the diorite-marble contact. The marble belt is flanked to the west and southwest by a narrow (200 m) metasedimentary unit and by mafic metavolcanics. One small finger of the McLean Pluton extends into the south-central portion of the marble belt.

Local Geology

689—The detailed map area consists almost entirely of white to light grey calcitic marble (Figure 50). The light grey colour is largely due to the presence of fine-grained graphite, which is concentrated in narrow bands parallel to the foliation. Dolomitic marble clots within the calcitic marble are recognized by a mottled texture, caused by the resistance of dolomite to weathering. These clots are often boudined parallel to the local foliation. Most of the marble is fine to medium grained, with only minor graphite and phlogopite as impurities. There is a narrow silicification zone at the intrusive contact, near the south end of the map area.

692—The marble belt narrows to only a few metres until it is finally truncated by the Mountain Grove Intrusion. The geology of this area consists of white to light grey calcitic marble with minor graphite and phlogopite, intruded and crosscut by metamorphosed granitic intrusions (Figure 51). The intrusive contact is partially silicified in places, but with only a few metres of alteration. There are also several narrow discontinuous schist units throughout this area.

Previous Geological Work

Olden Township has been mapped by Harding (1951), Hewitt (1964a), and Wolff (1982b).

Chemistry

There are four samples (samples 689 to 692) within a few hundred metres of the contact of the marble with the Mountain Grove Intrusion that have greater than 52 percent CaO and less than 1 percent SiO_2. All of the samples contain very low trace and metallic element contents.

Channel sampling within the two areas indicates that the SiO_2 content is variable across the zone. In map area 689, SiO_2 contents range from 1 percent to over 6 percent, while CaO contents are high (greater than 52 percent) throughout. Reflectivity is also variable, ranging from 44 to 77 percent.

Potential

The main part of the marble zone is made up of clean white to light grey marble, and warrants further investigation. There is minor graphite and phlogopite in the marble; however, this becomes less abundant in some bands.

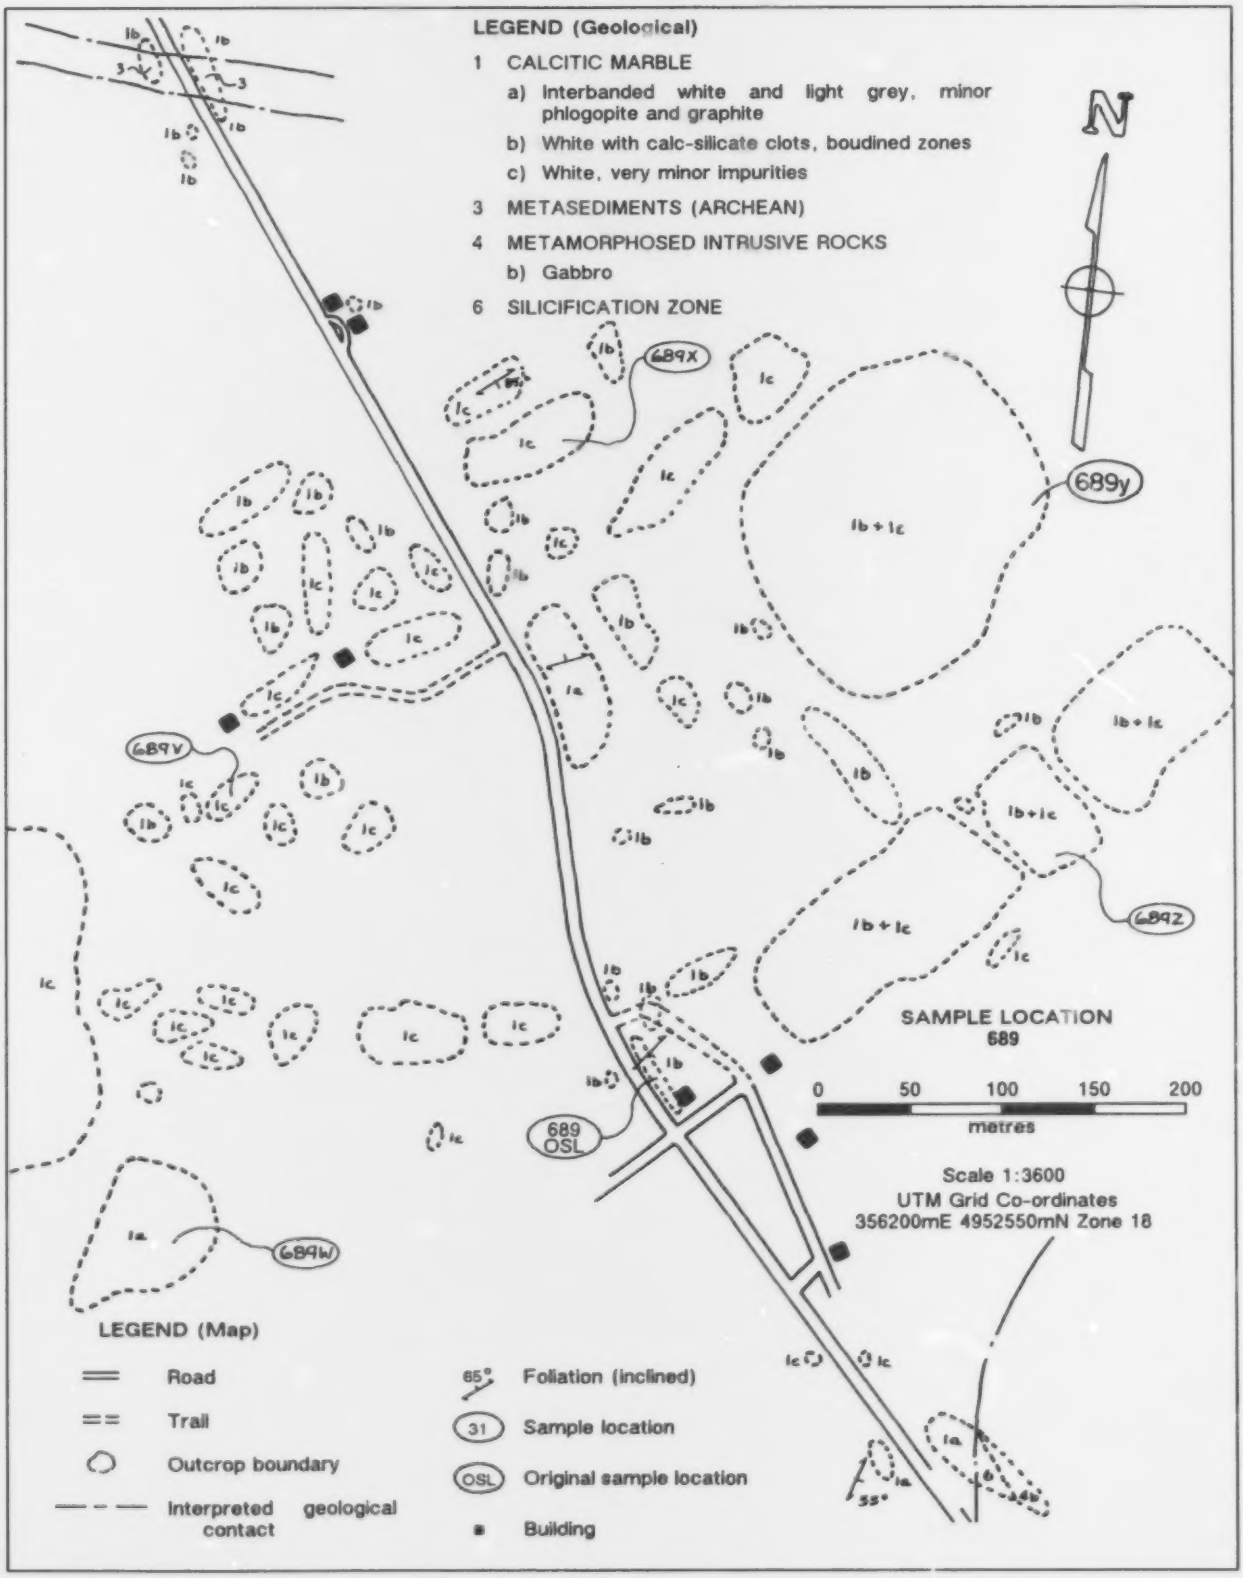

Figure 50. *Location Map, Sample 689.*

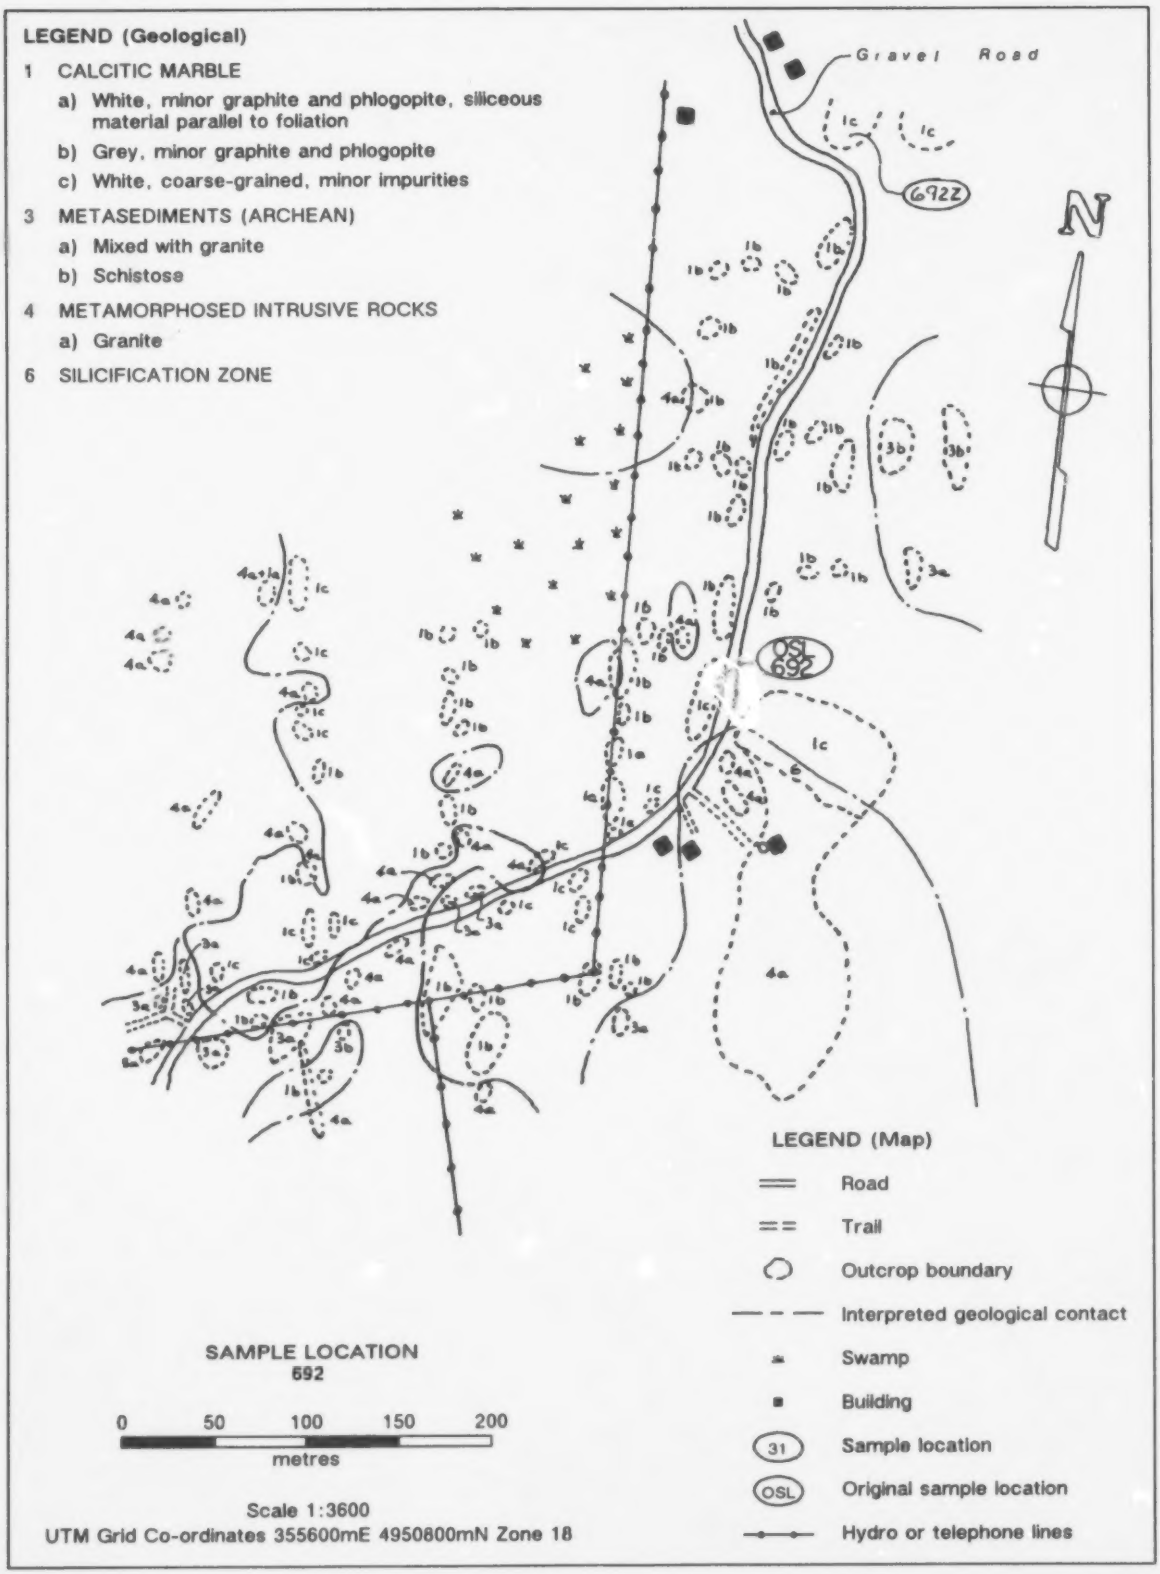

Figure 51. *Location Map, Sample 692.*

MAP AREAS 697, 698, AND 699

Location

All samples are from the northeast end of Long Lake, Olden Township.

Map reference: NTS 31C/10.

697—UTM 359700mE, 4949750mN, Zone 18.

698—UTM 362000mE, 4949300mN, Zone 18.

699—UTM 361600mE, 4949800mN, Zone 18.

Access

697—This is the former Long Lake Zinc Mine, Concession V, Lot 2.

698—On the main paved road from Mountain Grove, Concession VI, Lot 1.

699—On the main paved road from Mountain Grove, Concession VII, Lot 1.

Regional Geology

All of these samples are from small marble units surrounded by granitic and dioritic intrusive rocks. These marble units are remnants of a much larger marble belt which was intruded by a granitic/dioritic intrusion.

Local Geology

697—The marble unit from which this sample was taken occurs as an inlier within the Mountain Grove Intrusion (Figure 52). The marble is white, massive, and is medium to coarse grained with only minor phlogopite and black sphalerite. The marble unit is 150 to 200 m in surface width and approximately 650 m long.

698—The marble unit from which this sample was taken is in an intrusive unit adjacent to the Mountain Grove Intrusion. The marble unit strikes north-northeast with a maximum width of 50 m and a length of 400 m (Figure 53). There is also a thin parallel marble band about 100 m east of this main unit, which is only a few metres wide. Marble is generally coarse grained and white, with minor graphite plus phlogopite. The marble is blue to light green in colour at the southern end.

699—This sample is from a very small marble unit (Figure 54) that occurs within the Mountain Grove Intrusion. There is no evidence that the chemical composition of the marble has changed from that of its premetamorphic precursor; however, there is a zonation to clean white coarse-grained marble near the intrusive contacts, which may have been the result of restricted hydrothermal circulation at the marble-intrusive rock boundary.

Previous Geological Work

Olden Township has been mapped by Harding (1951), Hewitt (1964a), and Wolff (1982b).

Chemistry

Most of the marble samples (samples 697 to 700) taken from units within the Mountain Grove Intrusion and surrounding McLean Pluton are quite pure with less than 1 percent SiO_2. It is likely that the intrusion of the Mountain Grove Intrusion caused the recrystallization of the marble, thereby eliminating minor impurities from the crystal structure and leaving a purer end member marble.

Trace element and base metal contents are anomalous only at the Long Lake Zinc Mine (map area 697).

Potential

Marble in the area is white with a coarse grain size, indicating that the quality is good for industrial filler material. However, the marble zones examined are small in size, and a nearby larger zone would need to be discovered in order that the area be considered as having economic potential.

MAP AREAS 746 AND 1912

Location

746—South-central Dalhousie Township.

1912—Northwest Bathurst Township.

Map reference: NTS 31C/16.

746—UTM 385470mE, 4979190mN, Zone 18.

1912—UTM 381870mE, 4972570mN, Zone 18.

Access

746—3 to 4 km west of Playfairville on County Road 12, Concession V, Lot 1.

1912—11 km southwest of Fallbrooke on a gravel road, Concession XI, Lot 4.

Regional Geology

These samples are part of a wide northwest-trending metasedimentary-marble belt which is several kilometres in length. Flanking the marble portion of the belt is metasedimentary hornblende amphibolite paragneiss and paragneiss-marble migmatite. The marble is white to light grey and is dolomitic to calcitic in composition.

Local Geology

746—Marble in this detailed map area is predominantly light and dark grey laminated, with lesser amounts of dolomitic and white calcitic marble (Figure 55). Fine-grained grey marble in the area has minor visible impurities while coarser grained white marble contains visible pyrite, biotite, and minor amphibole. Outcrop is sparse in this area making it impossible to determine by examination of the surface geology alone the extent of white versus grey marble.

1912—Marble in this area (Figure 56) can be subdivided into two categories: a) white with minor impurities; and b) grey with minor impurities. Only one marble outcrop that would be considered impure occurs in the map area. White marble has a grain size of up to 3 mm and contains only minor amounts of graphite, pyrite, and phlogopite. Grey marble has a grain size of up to 8 mm and contains minor graphite and muscovite. Minor occurrences of dolomitic marble appear throughout the belt but cannot be traced over any distance. The marble unit terminates to the east with a paragneiss unit, which in turn is bounded by a metamorphosed granitic intrusion to the east.

Previous Geological Work

Dalhousie Township has been mapped by Smith (1958) and Hewitt (1964a). Bathurst Township has been mapped by Wilson and Dugas (1961) and Hewitt (1964a).

Chemistry

Marble samples taken throughout the entire belt (samples 725 to 806 and 1910 to 1928) are dominantly of calcitic composition, with less than 2 percent SiO_2. MgO content ranges from 6 to 8 percent. The marble of this belt contains low trace and metallic element contents.

One channel sample from each of these map areas has a low SiO_2 content and a high CaO content. Reflectivity is in the range of 61 to 68 percent.

Potential

Map area 746 tends to be dominated by fine-grained grey marble of high purity but low brightness. Map area 1912 has both white and light grey marble with only minor impurities occurring over a large area. It is possible that further investigation across strike would show an even larger amount of white marble. Up to 20 percent tremolite occurs in some outcrops and may be of interest as a by-product of marble extraction.

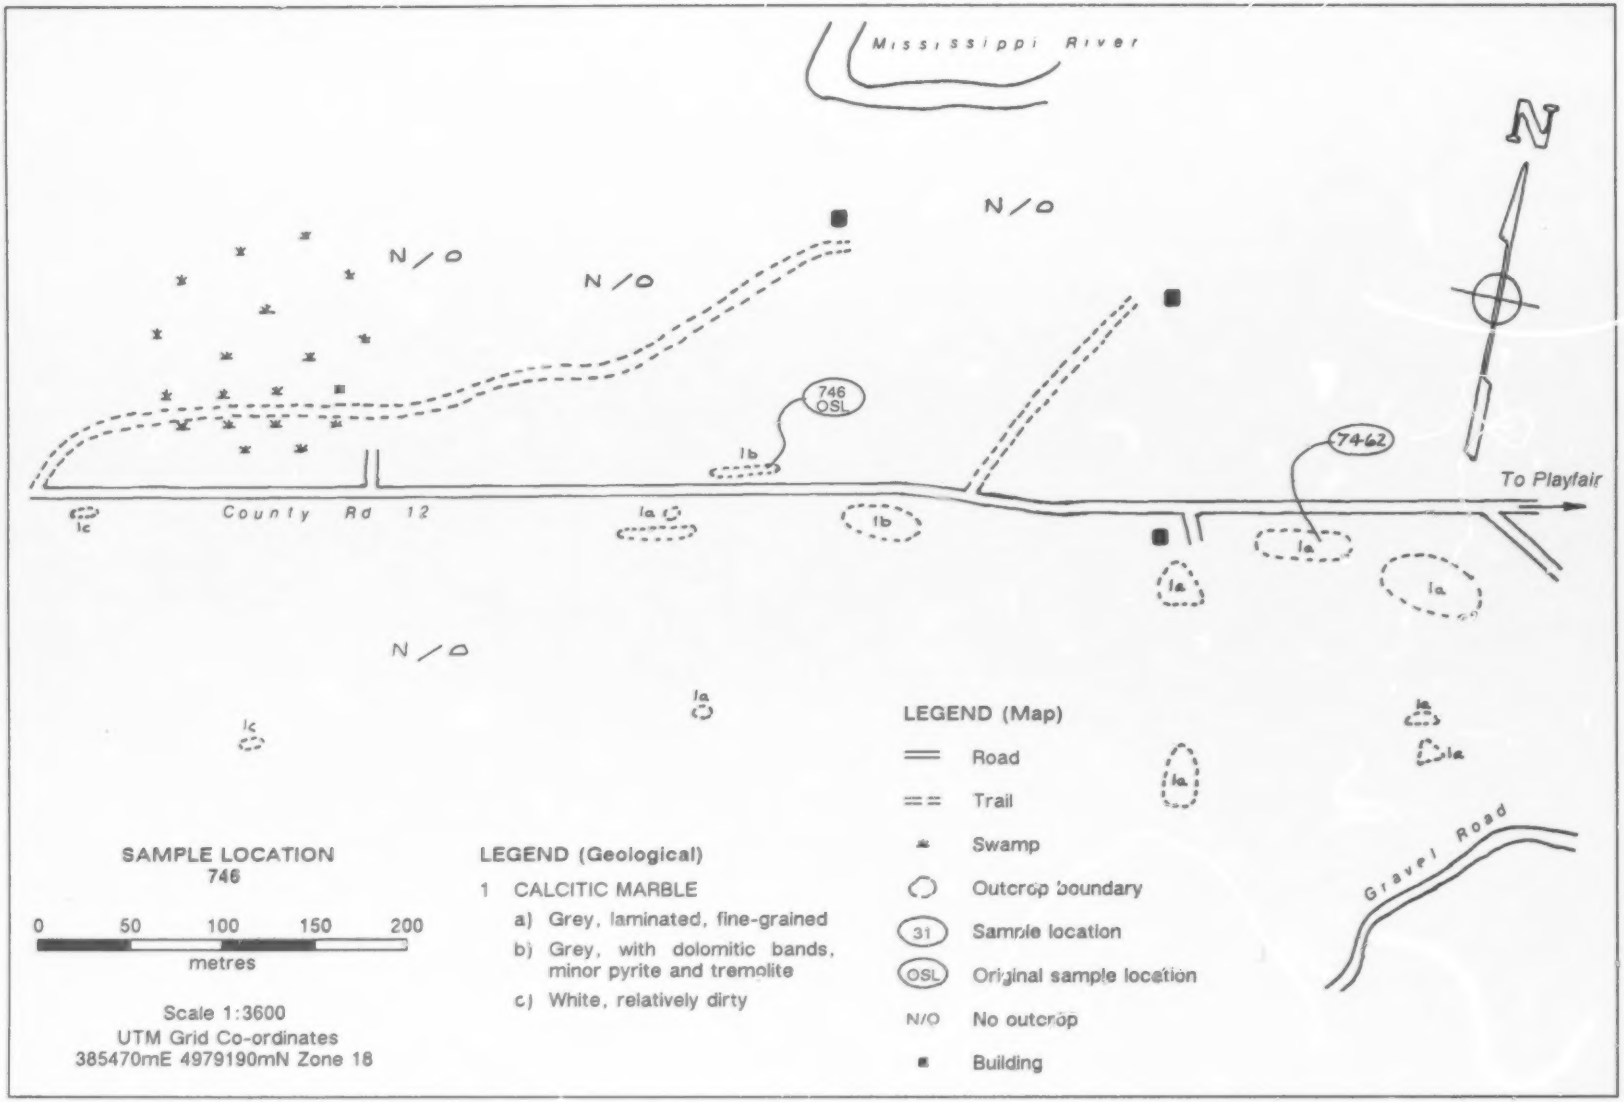

Figure 55. *Location Map, Sample 746.*

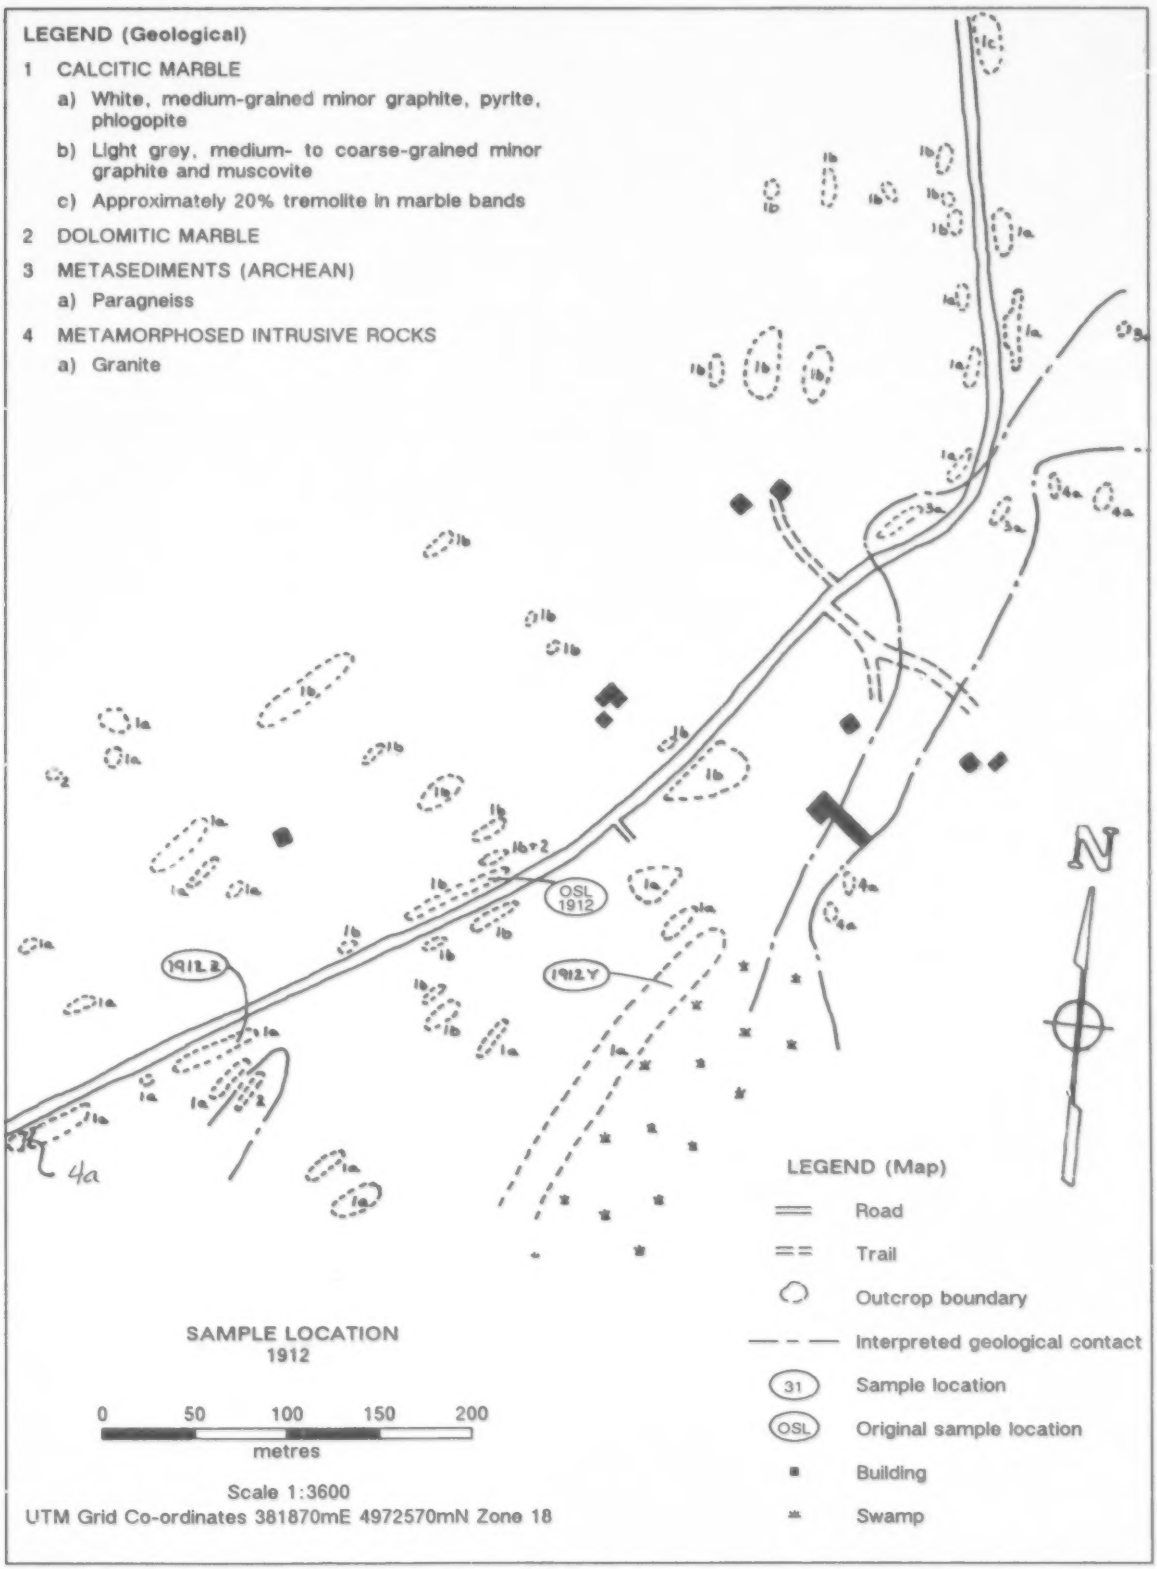

Figure 56. *Location Map, Sample 1912.*

MAP AREA 770

Location

Southern end of Dalhousie Township.

Map reference: NTS 31C/15; UTM 379200mE, 4981900mN, Zone 18.

Access

Approximately 1 km east of Dalhousie Lake, 2 km north of McDonalds Corners, on a northwest-trending road, Concession VII, Lot 11.

Regional Geology

This sample was taken from a wide marble belt which trends northeast across the southeastern corner of Dalhousie Township into Lanark and Ramsay Townships. This belt has numerous narrow metasedimentary, amphibolitic, and metaigneous units running parallel to, and contained within it. The belt is several kilometres wide in some areas and up to 20 km in length. It is flanked to the southeast by amphibolite where it is partially overlain by Ordovician sedimentary rocks, and to the northwest by metadiorite and amphibolite.

Local Geology

Detailed mapping indicates that the area is underlain predominantly by white calcitic marble (Figure 57). Occurring within the marble are several narrow granitic dikes, most trending in a north-northeast direction. Only minor impurities occur within the marble, with the exception of a couple of narrow tremolite-rich zones.

Previous Geological Work

Dalhousie Township has been mapped by Smith (1958) and Hewitt (1964a).

Chemistry

Samples from this portion of the marble belt (samples 725 to 806) have generally low SiO_2 contents. CaO contents are in the range of 51 to 54 weight percent, with MgO contents up to 5 weight percent. Trace and metallic element contents are low throughout the area.

Potential

The whiteness and chemistry of this marble makes it attractive as a filler material, although the presence of granitic veins is unfavourable. Exploration outside of the immediate sample location area might locate larger volumes of high-purity white calcitic marble.

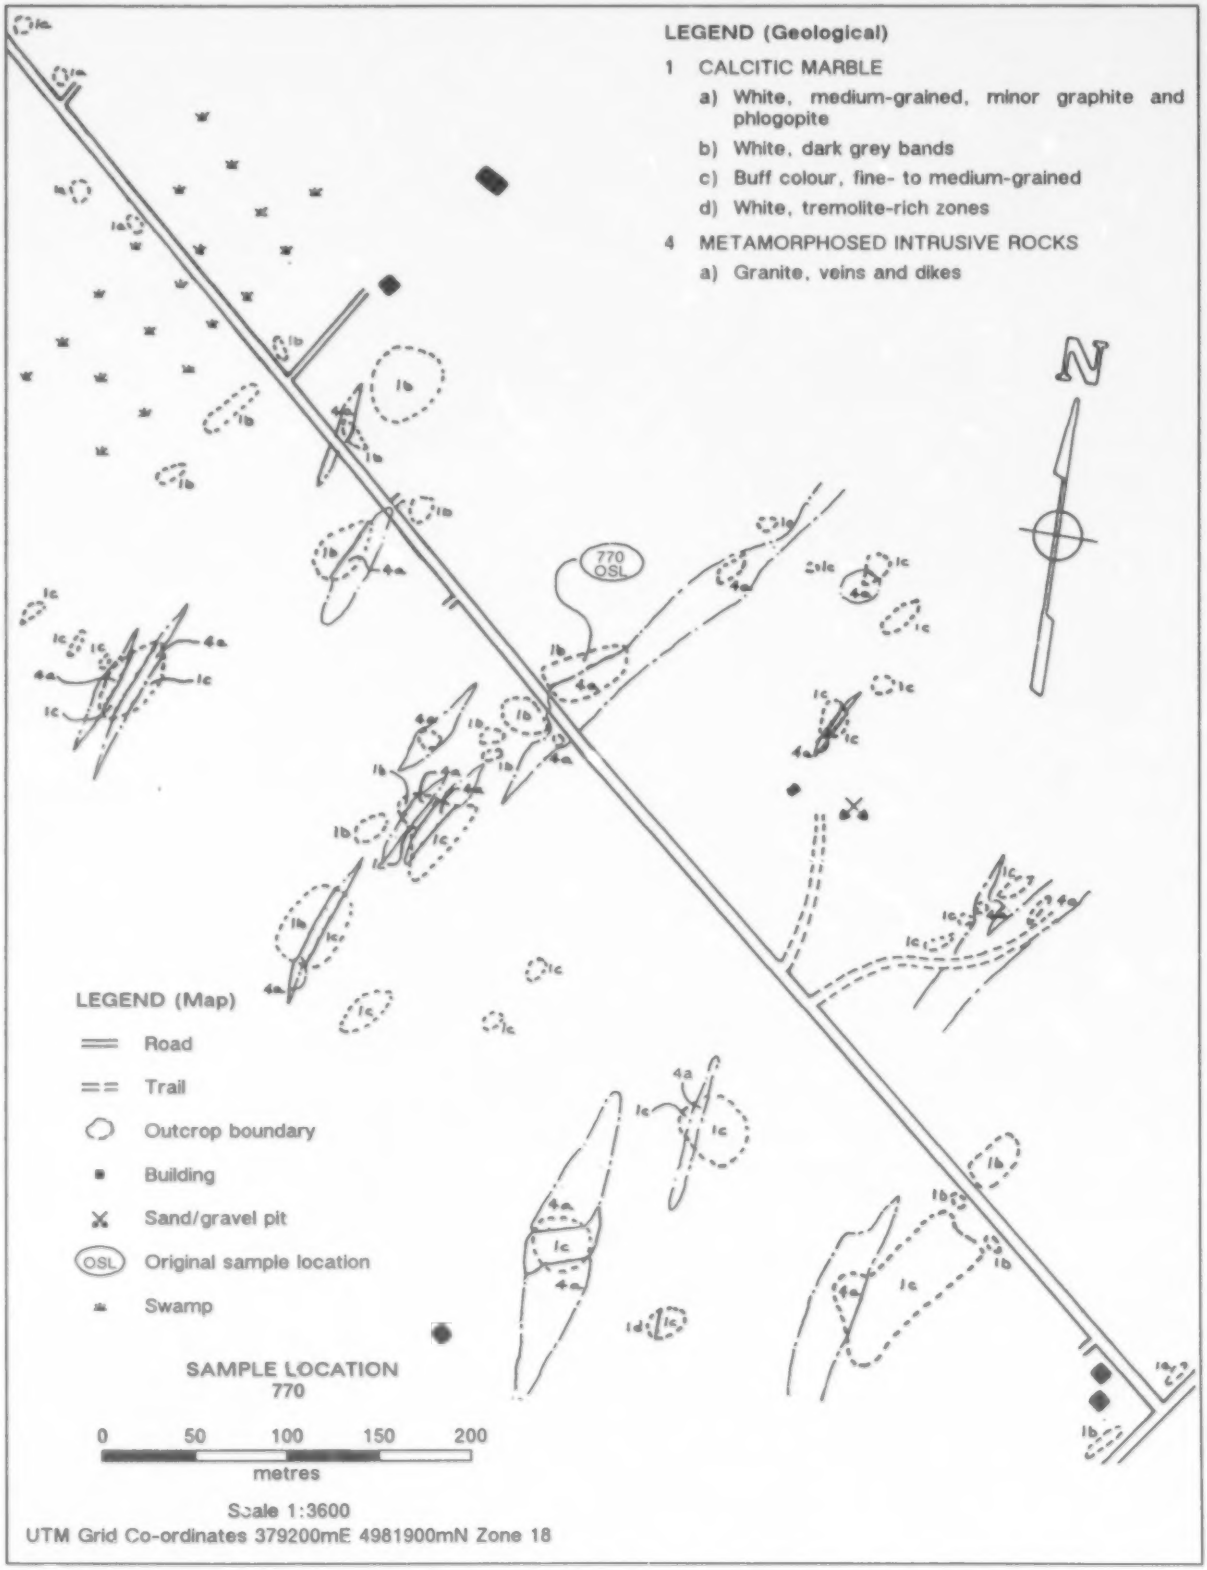

Figure 57. *Location Map, Sample 770.*

MAP AREA 818a/819

Location

Both samples were taken from the northeast corner of Denbigh Township

Map reference: NTS 31F/3.

818a—UTM 325080mE, 5009350mN, Zone 18.

819—UTM 324990mE, 5008500mN, Zone 18.

Access

Samples were taken along Highway 41 approximately 19 km north-northeast of Denbigh.

818a—Concession XIV, Lot 4.

819—Concession XV, Lot 4.

Regional Geology

The marble sampled in this area is part of the Dungannon Formation (Evans 1964), which is composed of two parallel units which are conformable to the surrounding metasediments. The metasedimentary unit flanking the marble on both sides is part of the Hermon Formation (Evans 1964) and interfingers with the marble. The area has been intruded by granitic rocks to the east of the sample location and also to the northwest by a separate granitic body. Marble in the belt is largely calcitic in composition, and contains minor graphite.

Local Geology

In the detailed map area (Figure 58), the calcitic marble is white with minor graphite and silicate minerals. There are a number of discontinuous dolomitic units, usually enclosed within the calcitic marble. There are also several hornblende amphibolite units conformable to the marble units, and one unit of garnetiferous mica schist near the south end of the map area. Some of the marble outcrops in the area also contain quartz and calc-silicate clots, which are randomly distributed throughout.

Previous Geological Work

Denbigh Township has been mapped by Evans (1964).

Chemistry

Most of the regional samples taken from this area (samples 816 to 820) are highly calcitic with CaO greater than 54 percent and SiO_2 less than 2 percent. Dolomitic marble occurs in the northern end of the belt, and also has a low SiO_2 content. Trace element and base metal contents are low throughout the marble belt.

Channel sampling in the map area indicates a nonuniform marble chemistry with SiO_2 ranging from 2 to 9 percent. Chemically, 818z is a dolomitic marble with $CaO/MgO \approx 1.4$. Reflectivity for both samples is high (74 to 76 percent).

Potential

The colour and fine grain size of the marble gives it good potential as filler-type material. However, the belt should be explored along strike in order to delineate those favourable areas where the dolomitic and metasedimentary units are absent.

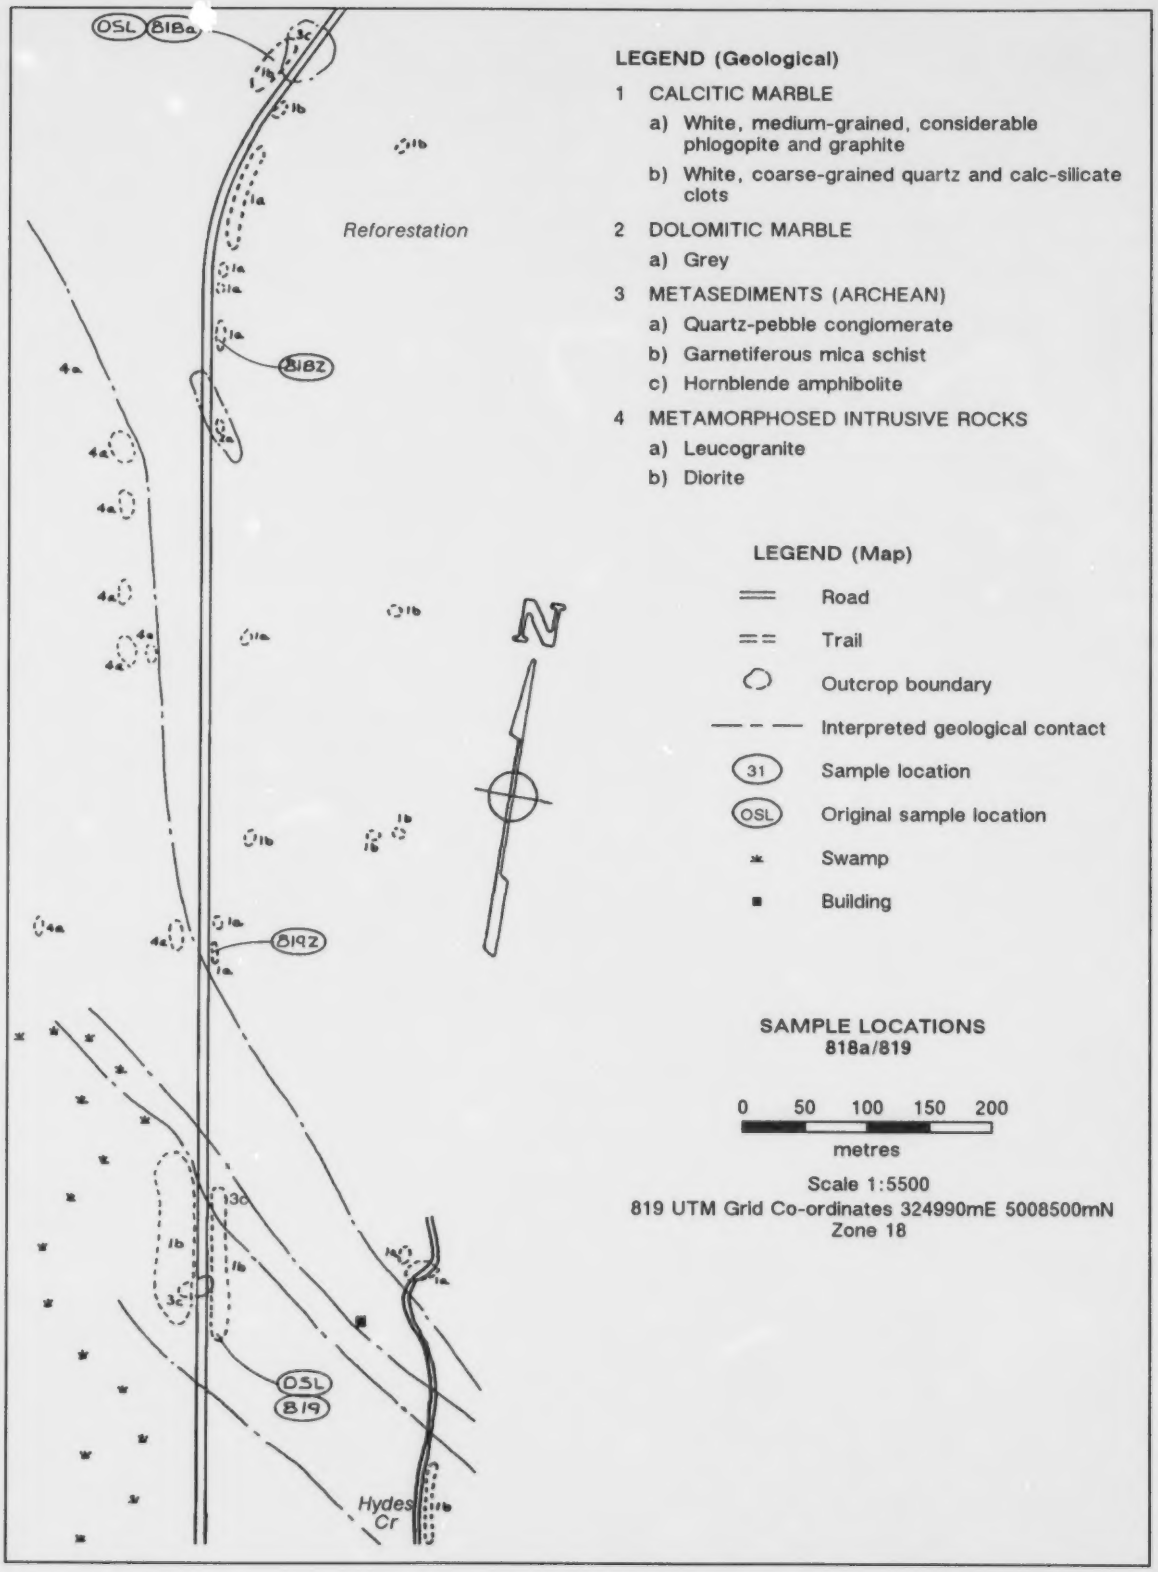

Figure 58. *Location Map, Samples 818a and 819.*

MAP AREA 1005

Location

Southeast corner of Storrington Township.

Map reference: NTS 31C/9; UTM 388750mE, 4914300mN, Zone 18.

Access

On a gravel road, 6 km west of Highway 15 at Ida Hill, Concession VII, Lot 6.

Regional Geology

This sample was taken from a relatively small marble unit, approximately 1 km wide by 3 km long. The unit is bounded to the southeast by leucocratic intrusive rocks and to the northwest by paragneiss. Several small paragneiss units occur within the marble unit.

Local Geology

Outcrops are scarce in the detailed map area (Figure 59), as much of the area is low lying geographically. The marble is very coarse grained, containing minor graphite and phlogopite as disseminated flakes. In some outcrops, areas of white silicate and calc-silicate material occur within the marble unit. These may be rafted blocks of a nearby unit or calc-silicate pods which formed *in situ*.

Previous Geological Work

Storrington Township has been mapped by Hewitt (1964a), and in part by Wynne-Edwards (1962, 1967).

Chemistry

Most of the samples from this belt (samples 1004 to 1021) have high SiO_2 contents and CaO/MgO ratios in the range of 8 to 40. The Sr contents are high in most of the samples from this belt, while other trace and metallic element contents are low.

Potential

Marble from this small unit contains considerable amounts of silicate material as clots and lenses. It is unlikely that the marble from this area could be used as filler-type material; however, it is possible that cleaner marbles do exist within the main belt to the north.

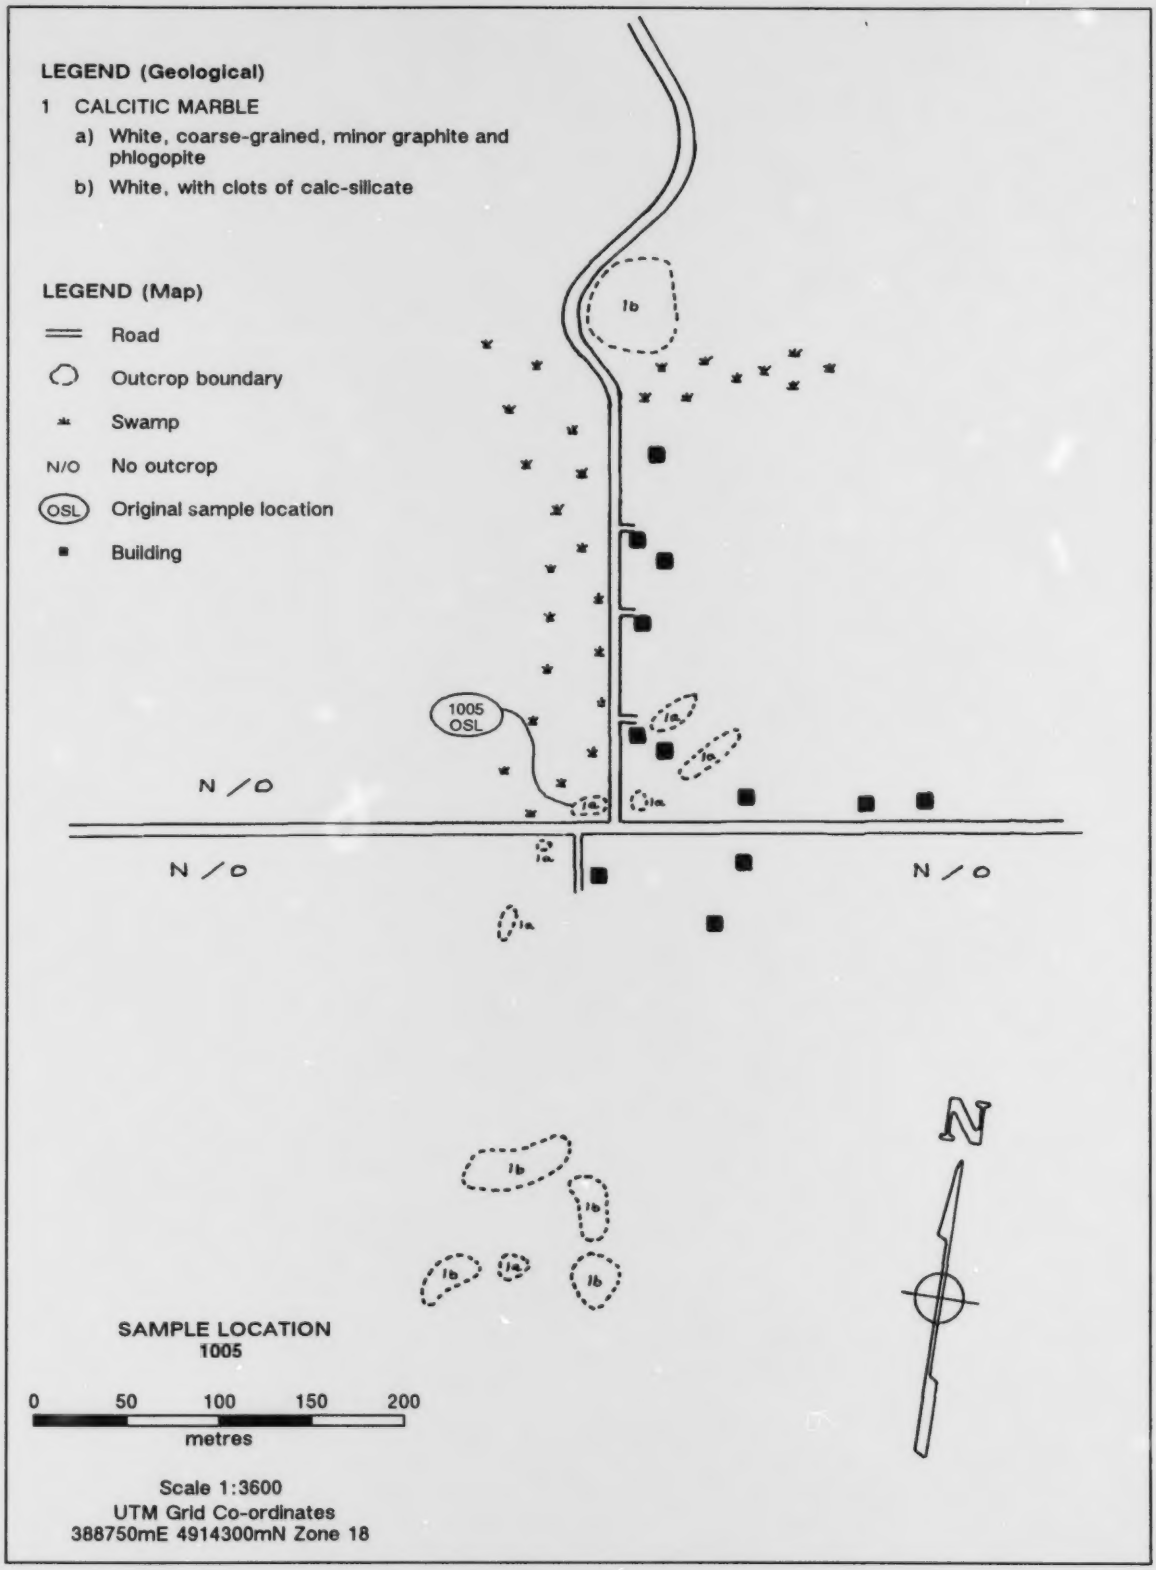

Figure 59. *Location Map, Sample 1005.*

MAP AREAS 1038 AND 1069

Location

1038—Northwestern Rear of Leeds and Lansdowne Township.

1069—Southwestern Rear of Leeds and Lansdowne Township.

Map reference:

1038—NTS 31C/8; UTM 404800mE, 4922100mN, Zone 18.

1069—NTS 31C/9; UTM 407100mE, 4929050mN, Zone 18.

Access

1038—On Highway 32, 1.5 km north of South Lake.

1069—On the road through Lyndhurst, 300 m northwest of Grippen Lake.

Regional Geology

These samples were taken from the central portion of a wide northeast-trending metasedimentary-marble belt which underlies most of Rear of Leeds and Lansdowne Township. Within this wide belt are several igneous intrusions, some of which are conformable to the structure of the belt.

Local Geology

1038—Marble in this map area is white and coarse grained with varying amounts of graphite, pyrite, and phlogopite (Figure 60). Within the marble are small metasedimentary layers which are a few centimetres to a metre in thickness. Siliceous metasedimentary layers divide the marble into several narrow bands. In the southern portion of the map area is a Paleozoic conglomerate and red sandstone cap rock.

1069—This sample was taken from the southern end of the marble belt where it tends to widen to several hundred metres from the approximately 100 m width in the northern part of the belt. Within the map area (Figure 61) are several rusty schist (metasedimentary) units only a few centimetres in width and usually only 1 m in length. The marble belt is flanked to the east and west by syenitic intrusive rocks which grade locally to a more dioritic composition. Marble is coarse grained, white, and very friable. Impurities include graphite, phlogopite, and small clots of silicate material.

Previous Geological Work

Rear of Leeds and Lansdowne Township has been mapped by Hewitt (1964a) and in part by Wynne-Edwards (1962, 1967).

Chemistry

Most of the samples taken in this belt (1011 to 1021, 1038 to 1040, 1069, and 1118 to 1132) have high SiO_2 and low CaO contents. Two of the samples have high Sr contents, while the rest have low trace and metallic element contents.

One channel sample taken in area 1038 has a greater than 5 percent SiO_2 content, with a reflectivity of only 56 percent.

Potential

In the immediate areas surrounding the sample locations, the high impurity content in the marble makes it unfavourable as a filler material. It is possible that other areas in the marble belt have lower impurity contents, and an emphasis should be put on locating these areas.

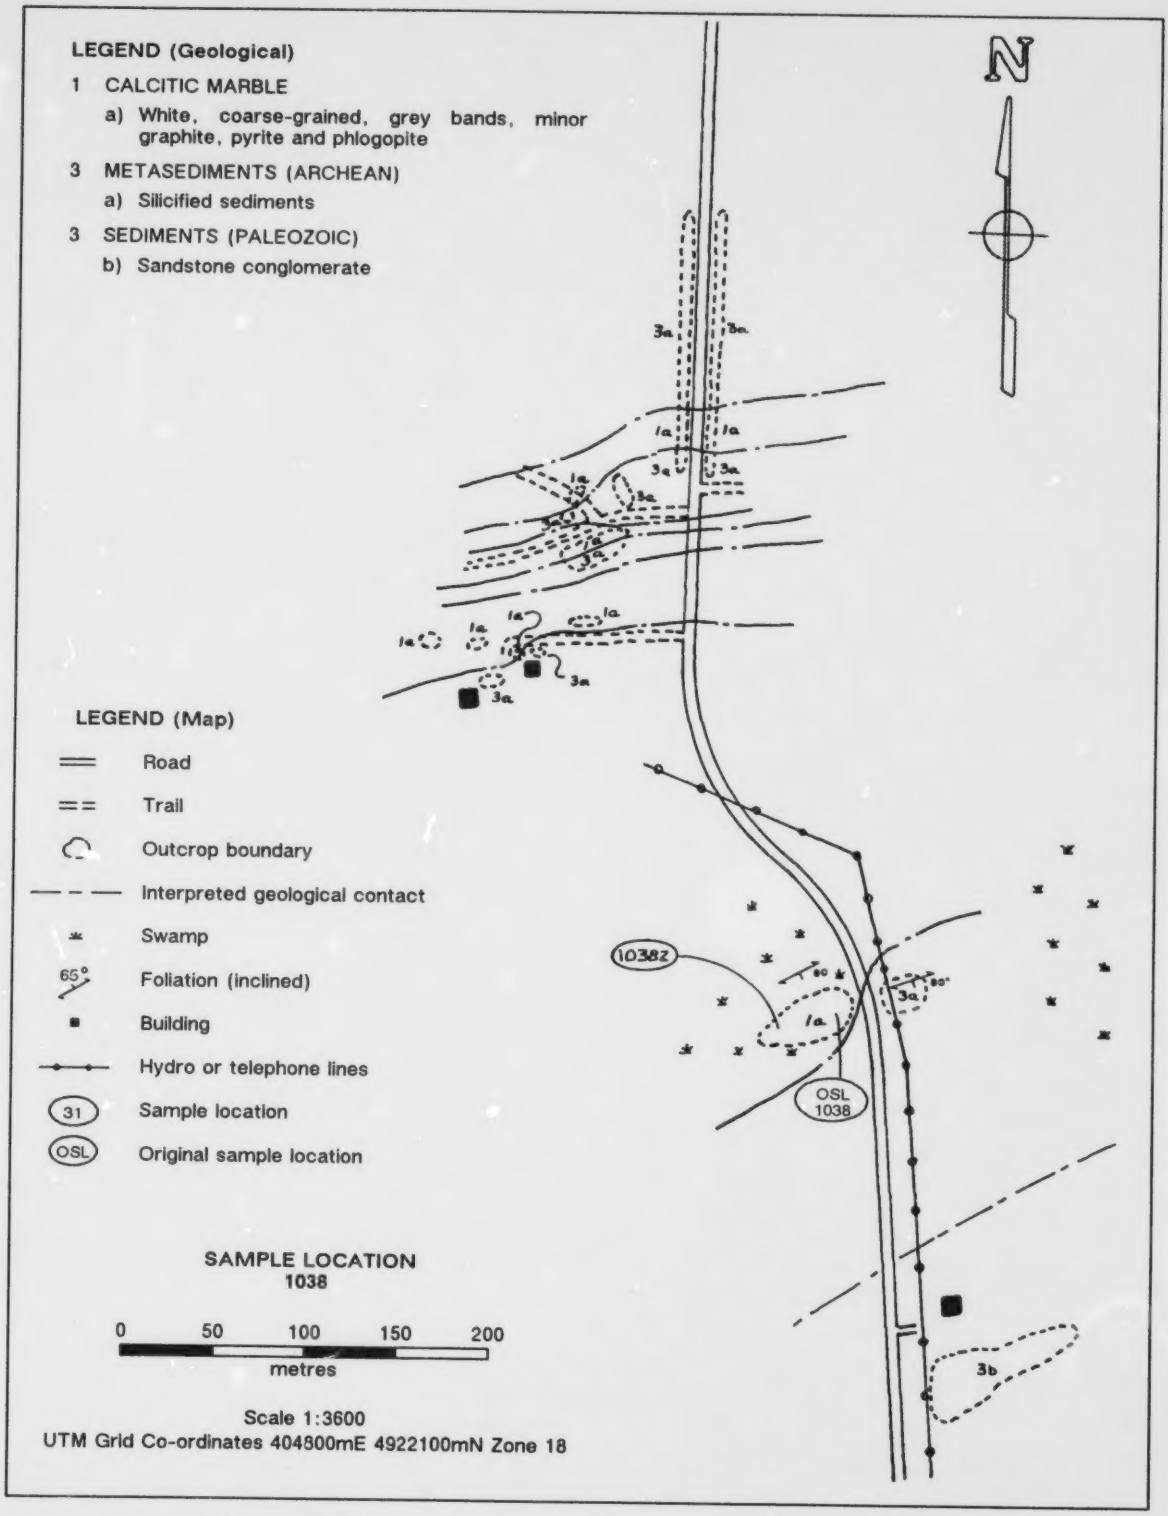

Figure 60. *Location Map, Sample 1038.*

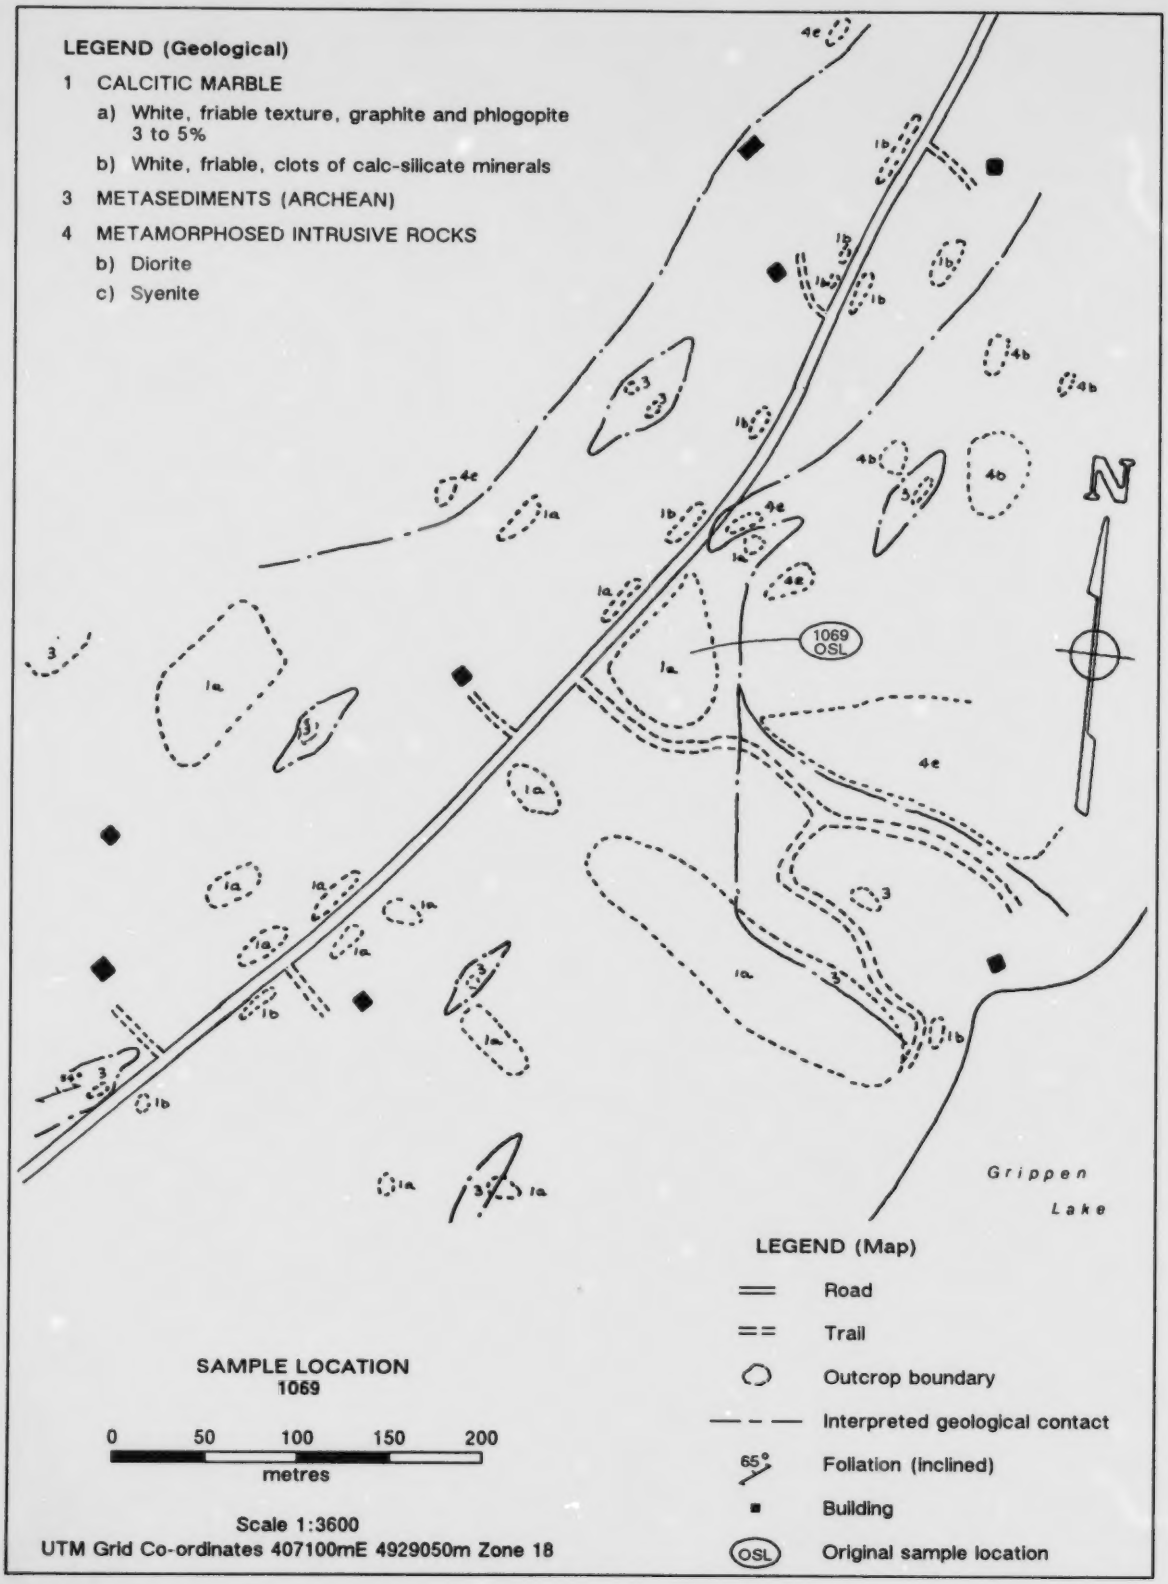

Figure 61. *Location Map, Sample 1069.*

MAP AREAS 1055 AND 1079

Location

South-central part of Rear of Leeds and Lansdowne Township.

Map reference:

1055—NTS 31C/8; UTM 416100mE, 4926700mN, Zone 18.

1079—NTS 31C/9; UTM 416700mE, 4928850mN, Zone 18.

Access

1055—On the main road running through Lansdowne, 500 m west of Mud Bay, Concession VII, Lot 14.

1079—The south shore of Killingbeck Lake, a few hundred metres west of Charleston Lake Provincial Park, Concession VII, Lot 14.

Regional Geology

These samples were taken from a relatively narrow marble belt trending north-northeast through Charleston Lake (40 km south of Perth). Map area 1079 is flanked by paragneiss on both sides, and map area 1055 is almost completely surrounded by coarsely crystalline leucocratic granite.

Local Geology

1055—This detailed map area (Figure 62) has relatively coarse-grained white and buff-coloured marble. The eastern section of the map area is underlain by leucocratic granitic intrusive rocks. Much of the marble is relatively clean with only minor phlogopite, muscovite, and graphite. Orange marble in the area is associated with narrow serpentine zones.

1079—This map area (Figure 63) has a relatively small amount of marble, which is flanked by a narrow band of felsic igneous material (felsite) and by garnetiferous gneiss. The marble is coarse grained, white, and contains minor graphite and phlogopite. Some of the calcitic marble contains minor amounts of dolomitic marble. The felsite dikes are discordant with the marble and paragneiss.

Previous Geological Work

Rear of Leeds and Lansdowne Township has been mapped by Hewitt (1964a) and in part by Wynne-Edwards (1962, 1967).

Chemistry

SiO_2 content within this relatively small marble zone (samples 1054 to 1057 and 1079) ranges from 1 to nearly 10 percent, although most samples have only 3 to 4 weight percent. CaO content is near 50 percent while MgO is less than 4 percent. Trace and metallic element contents are low throughout, with the exception of sample 1054 (Appendix A) which has a high Sr content.

Channel sampling in the area indicates a uniform chemistry, with SiO_2 between 1 and 2 percent. Sample 1055z has a low (41 percent) CaO content. Reflectivity is between 60 and 62 percent, which is low for white marble.

Potential

The whiteness and low impurity content of the marble make it an attractive source of filler material. It should be noted that this area is an important tourist park region.

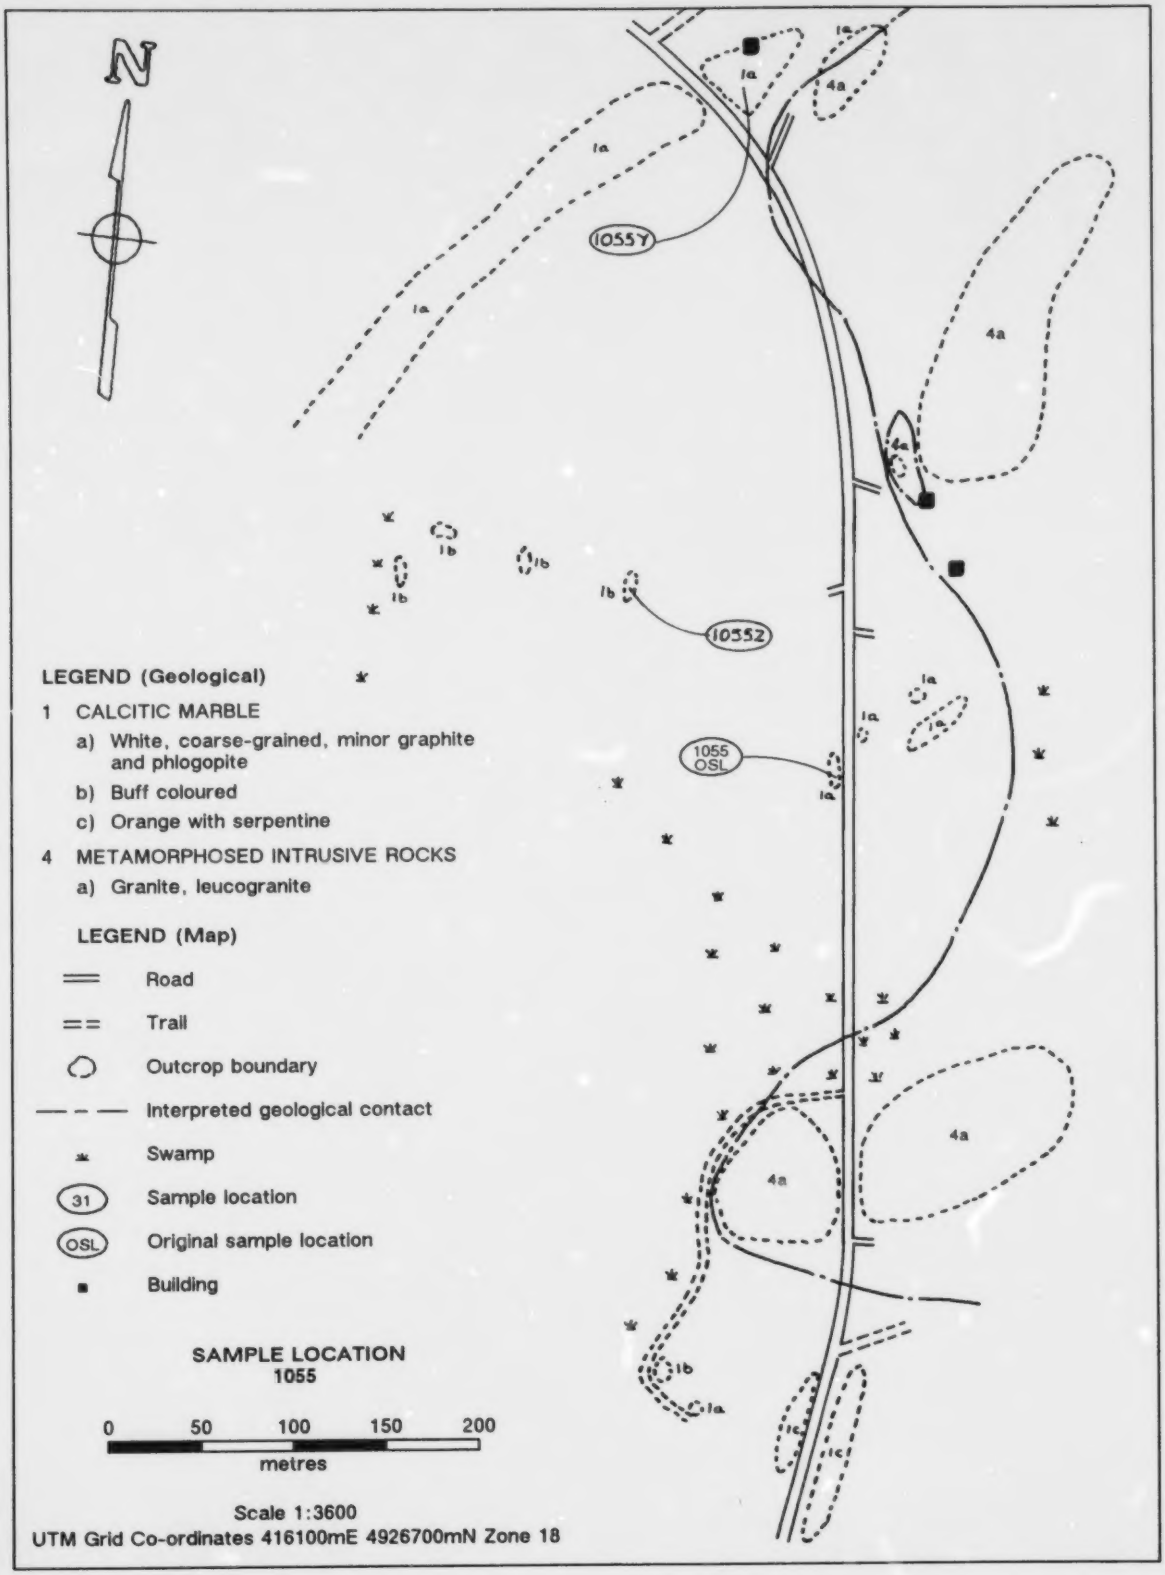

Figure 62. *Location Map, Sample 1055.*

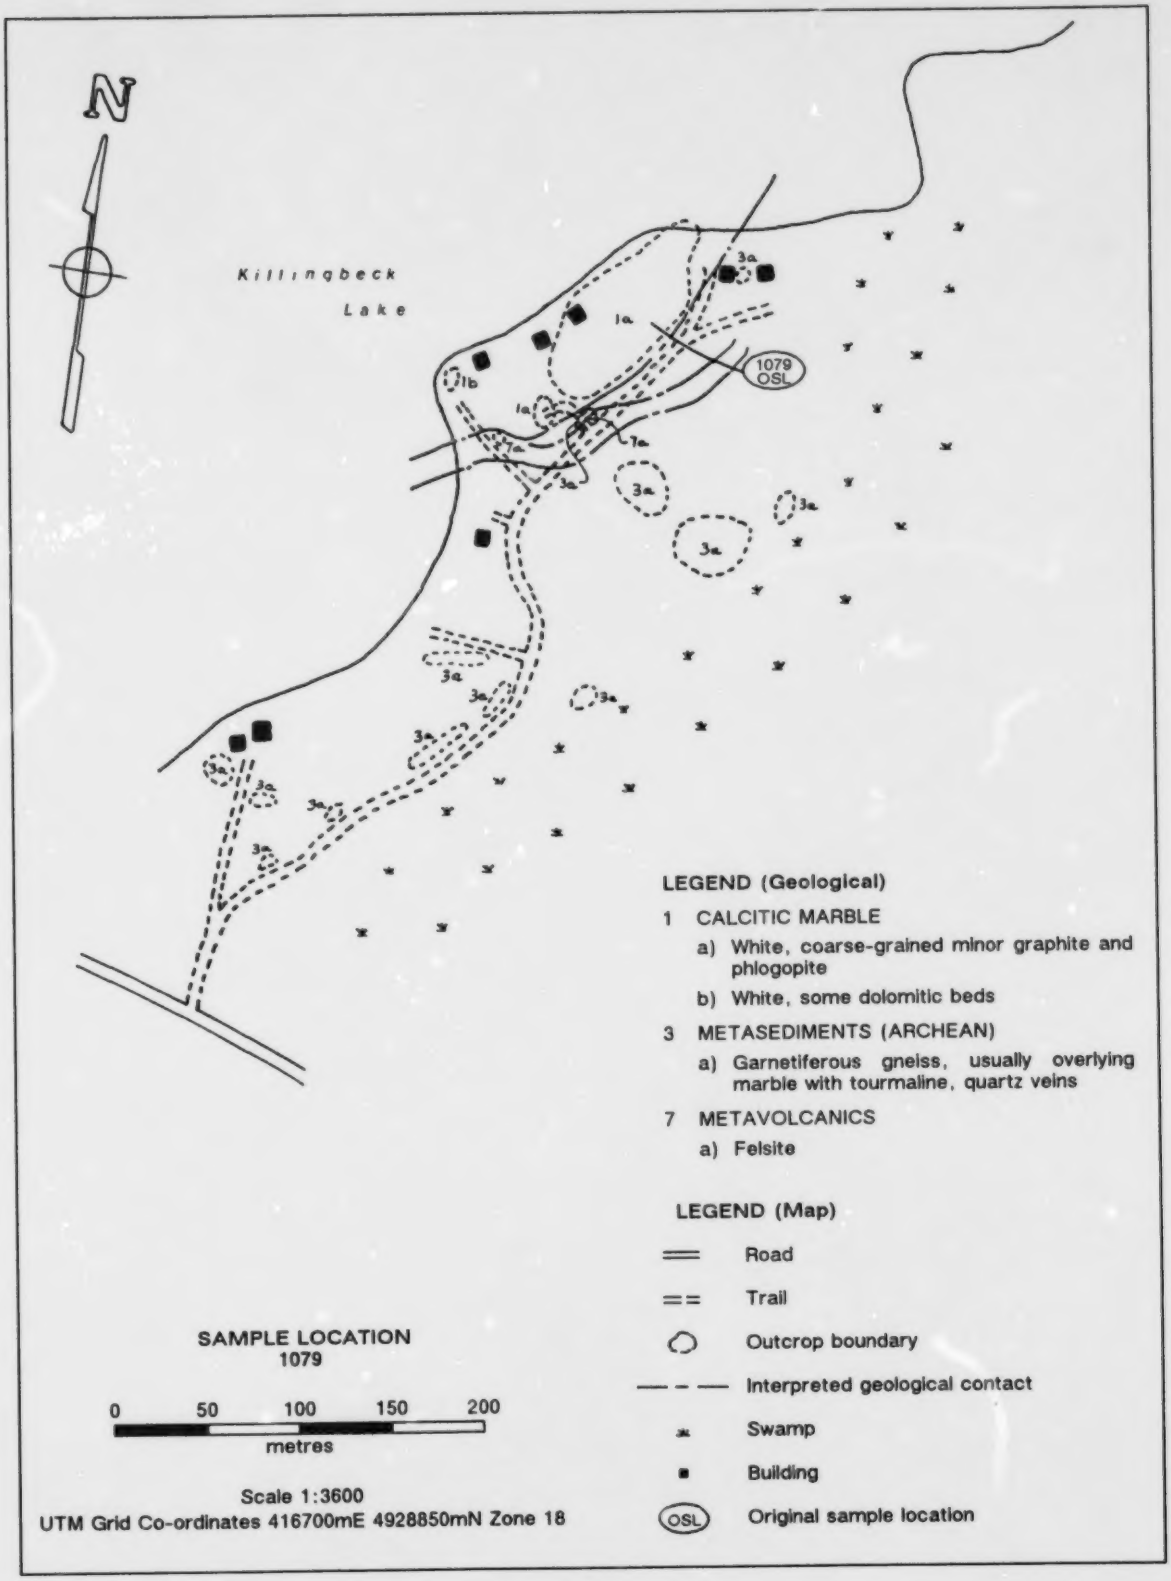

Figure 63. *Location Map, Sample 1079.*

MAP AREA 1076

Location

Rear of Leeds and Lansdowne Township.

Map reference: NTS 31C/9; UTM 411350mE, 4928350mN, Zone 18.

Access

5 km south of Lyndhurst on Leeds and Grenville Road 3, Concession VIII, Lot 2.

Regional Geology

Marble within this belt is generally coarse, white, and massive in texture. Within the belt are numerous small "white pegmatite" clots, and also larger white pegmatitic bodies of medium grain size (Wynne-Edwards 1962).

Local Geology

The detailed map area (Figure 64) indicates that several concordant igneous bodies occur within the marble unit. Marble is white and coarse grained with minor phlogopite and graphite. Clots of coarse-grained plagioclase (pegmatite), or "silicate segregations", occur in nearly all of the marble outcrops. Several of these segregations contain graphite and tourmaline as well as silicate minerals. Marble inclusions within the clots indicate that the segregations formed *in situ*.

Previous Geological Work

Rear of Leeds and Lansdowne Township has been mapped by Wynne-Edwards (1962, 1967) and Hewitt (1964a).

Chemistry

Marble samples in this belt (1048, 1049, 1076, 1078, and 1080) to have very high CaO contents and low MgO contents. CaO/MgO ranges from 1.4, which is the ratio for pure dolomite (and hence dolomitic marble), up to 120, indicating a highly calcitic marble. Almost all of the calcitic marble samples contain high Sr contents (greater than 1000 ppm), while the dolomitic marble samples have low Sr values (less than 400 ppm). All other metallic and trace element contents are very low.

Potential

The large amount of silicate material present in clots and pegmatitic bodies suggests that the marble in this area has a low potential for the development of fillers.

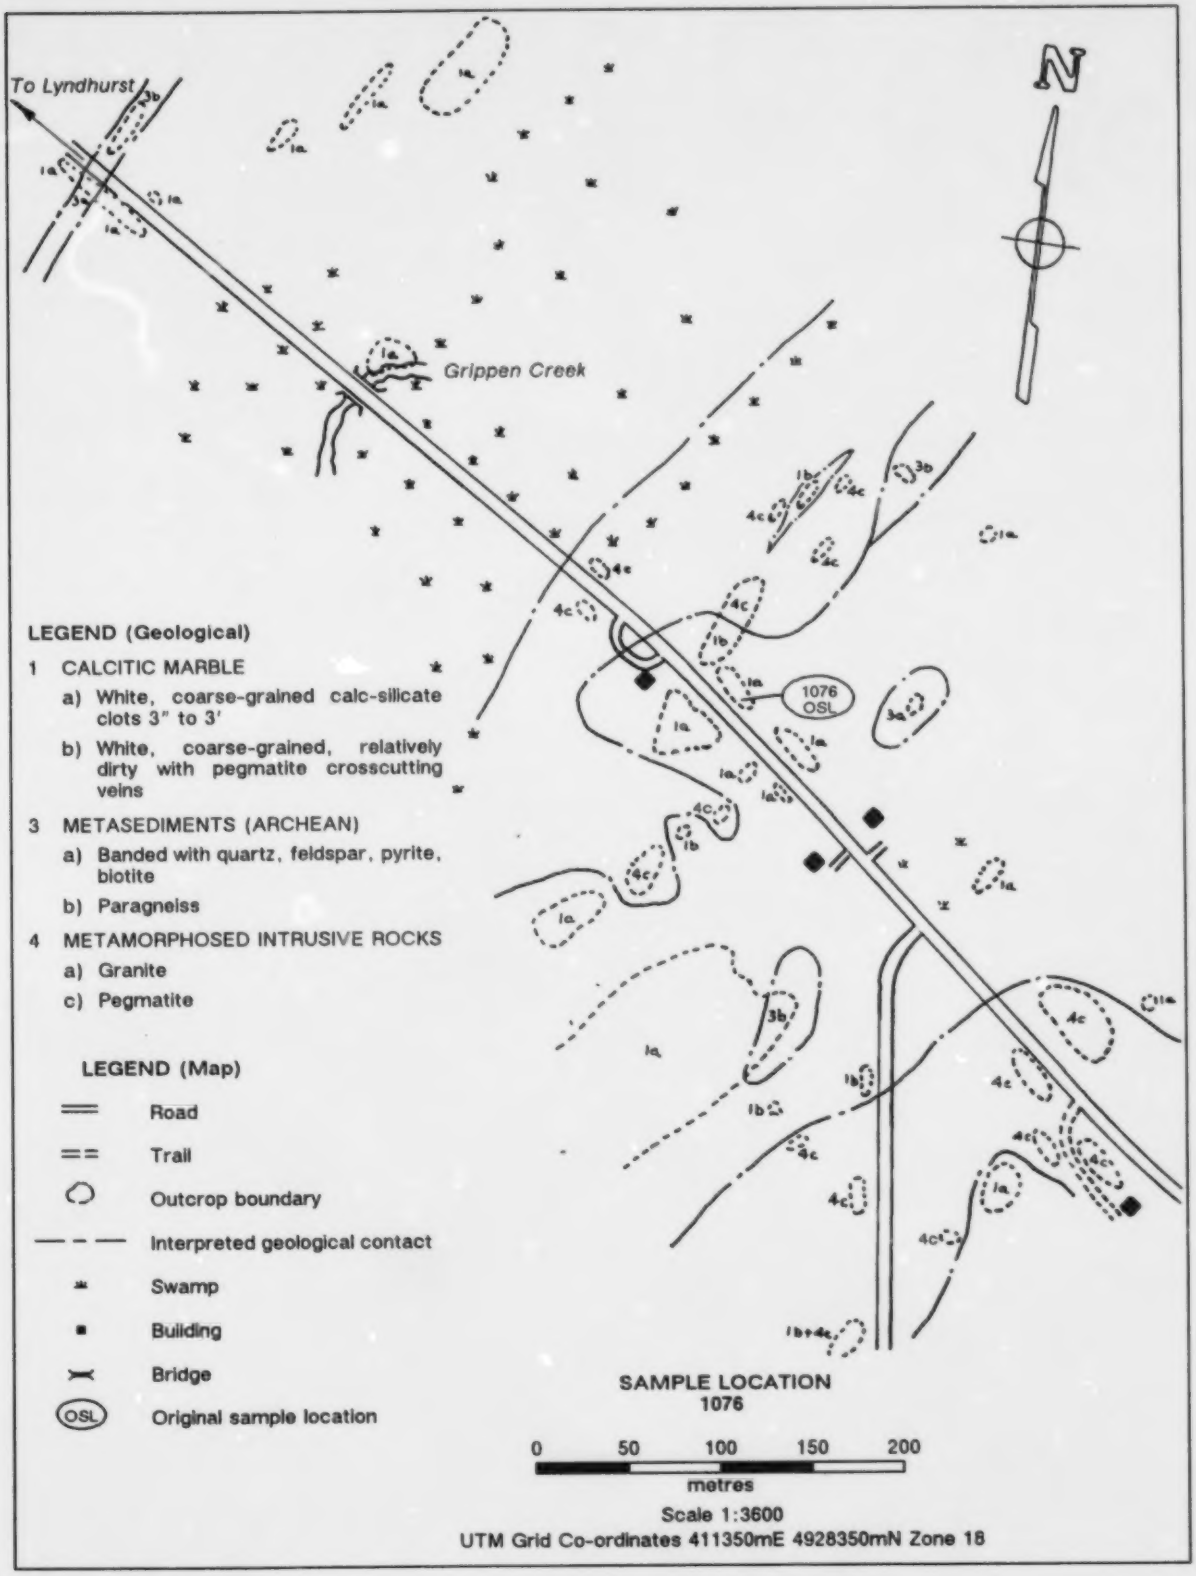

Figure 64. *Location Map, Sample 1076.*

MAP AREA 1082

Location

Rear of Leeds and Lansdowne Township.

Map reference: NTS 31C/9; UTM 412650mE, 4931150mN, Zone 18.

Access

A gravel road, 3 km southeast of Lyndhurst, Concession IX, Lot 6.

Regional Geology

This sample was taken from a large metasedimentary belt located west of Charleston Lake. The marble component of this belt was intruded by the Lyndhurst quartz monzonite intrusion. Marble is interbedded with metasediments and is intruded locally by leucocratic igneous rocks. These white igneous rocks are always associated with marbles in the Westport area (Wynne-Edwards 1967).

Local Geology

The sample taken from this location did not fit the original chemical limits of marble units chosen for mapping and detailed examination, but field examination of the area indicated that there was good-quality material present. There is a strong structural orientation of marble and metasediments in the map area indicating a strike of N30°E (Figure 65). Metasedimentary units are discontinous, as are silicate segregations. Marble is white and coarse grained, containing minor amounts of graphite and phlogopite. Silicate segregations occur from less than 1 cm to approximately 1 m in size, and appear to have formed within the marble rather than being rafted blocks of a nearby unit.

Previous Geological Work

Rear of Leeds and Lansdowne Township has been mapped by Wynne-Edwards (1962, 1967) and Hewitt (1964a).

Chemistry

Several of the samples in this belt (1070 to 1075, 1077, 1081 to 1085) have CaO/MgO ratios greater than 20. SiO_2 content varies across the belt, as does MgO content. Most samples have low trace and metallic element contents except for Sr, which is anomalously high (greater than 1000 ppm) in the calcitic marbles.

Potential

There appears to be several zones of high CaO/MgO ratios in the belt, but only zones containing few if any metasedimentary and silicate inclusions are of interest. More detailed mapping may reveal these zones.

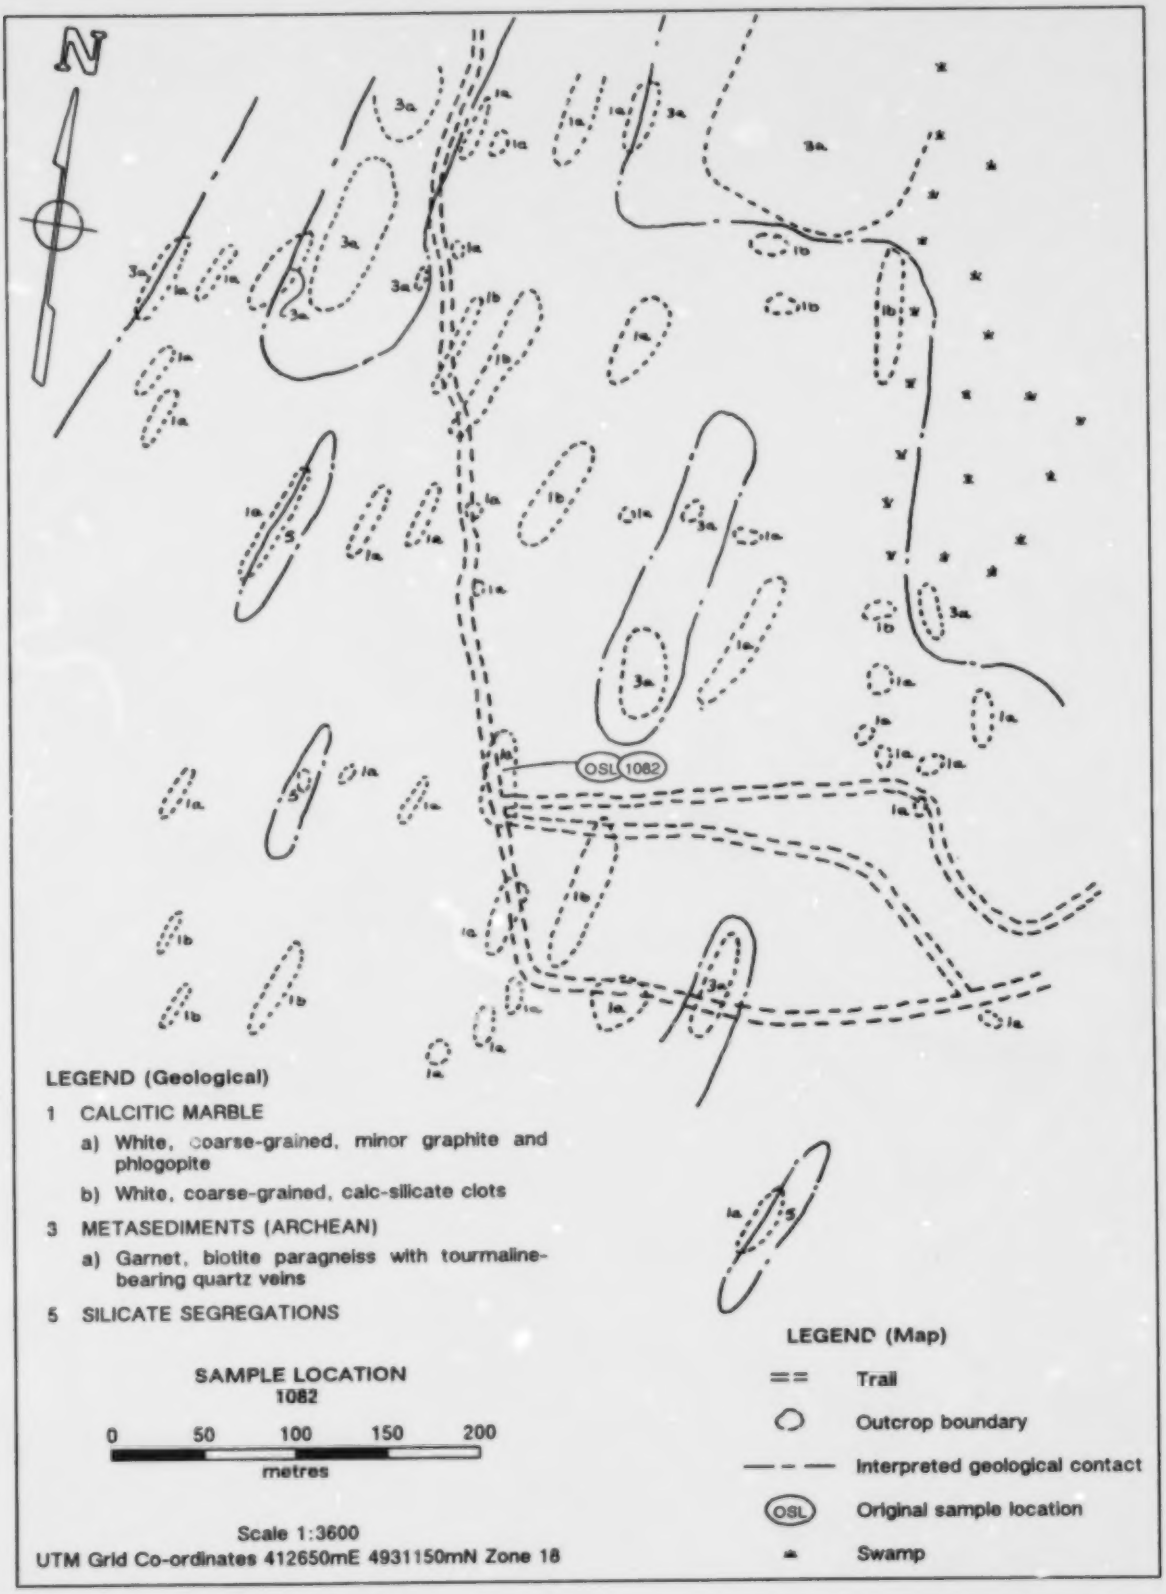

Figure 65. *Location Map, Sample 1082.*

MAP AREAS 1119 AND 1129

Location

1119—Northwest corner of South Crosby Township.

1129—Northwest corner of Storrington Township.

Map reference: NTS 31C/9.

1119—UTM 393100mE, 4938250mN, Zone 18.

1129—UTM 389000mE, 4929500mN, Zone 18.

Access

1119—2 km northwest of Chaffeys Locks at Indian Lake, Concession IX, Lot 21.

1129—On a gravel road, 9 km southwest of Chaffeys Locks, Concession XIII, Lot 10.

Regional Geology

This marble unit is part of a much wider metasedimentary belt trending northeast. The marble is flanked on both sides by quartz-feldspar gneiss and paragneiss. Within the marble is a unit of white intrusive rock, a common association which has been described at other localities. There are minor paragneiss units within the marble belt.

Local Geology

1119—The marble unit in this map area is approximately 100 m wide (Figure 66), with narrower units to the west of this main band. The northwest edge of this marble unit is bounded by white plagioclase-rich rocks (silicate segregations) which are exclusively associated with the marble zones. The southeastern edge of the marble belt is bounded by dioritic and gabbroic intrusive rocks, which are dark grey in colour with some minor white silicate pods. Marble is predominantly white with grey bands, and contains minor amounts of graphite and phlogopite.

1129—The marble zone is much wider in this map area (Figure 67) but has the same structure as that of map area 1119. There are no major metasedimentary units and only one small occurrence of white silicate material (unit 5) as a discontinuous pod. Marble is white with only minor phlogopite and graphite; siliceous clots also occur in some outcrops. Chlorite and muscovite also occur locally.

Previous Geological Work

South Crosby Township has been mapped by Wynne-Edwards (1962) and Hewitt (1964a). Storrington Township has been mapped by Hewitt (1964a) and by Wynne-Edwards (1962, 1967).

Chemistry

Most of the samples taken from this belt (samples 1115 to 1132) have high CaO contents and correspondingly low MgO contents. SiO_2 contents range from less than 1 percent to greater than 20 percent, but most samples have SiO_2 around 2 percent. Nearly all of the samples have very high Sr contents, but other trace and metallic element contents are low.

Channel sampling in the area indicates that the bedrock consists of an impure calcitic marble, with CaO/MgO ratios between 4 and 10. SiO_2 composes up to 10 percent of the total sample. Reflectivity is also low (56 to 60 percent).

Potential

The high CaO/MgO ratio and overall fairly low SiO_2 content in the marble make this an area of interest. Marble is generally white, and it may be possible to find zones where silicate clots do not exist.

MAP AREA 1162

Location

West-central North Burgess Township.

Map reference: NTS 31C/9; UTM 394650mE, 4954550mN, Zone 18.

Access

Along a gravel road, 1 km south of Black Lake, Concession V, Lot 26.

Regional Geology

The marble in this area is intruded by red monzonite displaying a conical zonation from red (away from the marble) to white (at the marble-monzonite contact), near the intrusive margins. North of the marble are migmatites made up of granite and metasediments.

Local Geology

The detailed map area shows that relatively little marble occurs in the area (Figure 68). Monzonite makes up the largest part of the bedrock and contains numerous pods and lenses of rusty metasediments and marble. Marble and metasedimentary units tend to be continous toward the western margins of the area. Marble is white and contains varying amounts of graphite and phlogopite. Some small zones have greater than 20 percent silicate material. Dolomitic marble occurs near the northern limit of the map, adjacent to the rusty metasediments.

Previous Geological Work

North Burgess Township has been mapped by Hewitt (1964a), and in part by Wilson and Dugas (1961).

Chemistry

The chemical composition of the marble in this area (samples 1150 to 1166) 1166) is inconsistent. A few samples are of calcitic marble type, but the majority have a wide range of CaO and MgO values with the CaO/MgO ratio ranging from 1.4 to 40. Several samples in the belt have high Sr contents, but this occurs only in those samples with high CaO/MgO ratios. Two samples also have high lead contents; it is interesting to note that these samples have relatively high SiO_2 contents as well.

Potential

Marble quality is quite variable throughout the unit, making it unlikely that a large section of good-quality marble could be found. It is more likely that several small high-grade zones exist.

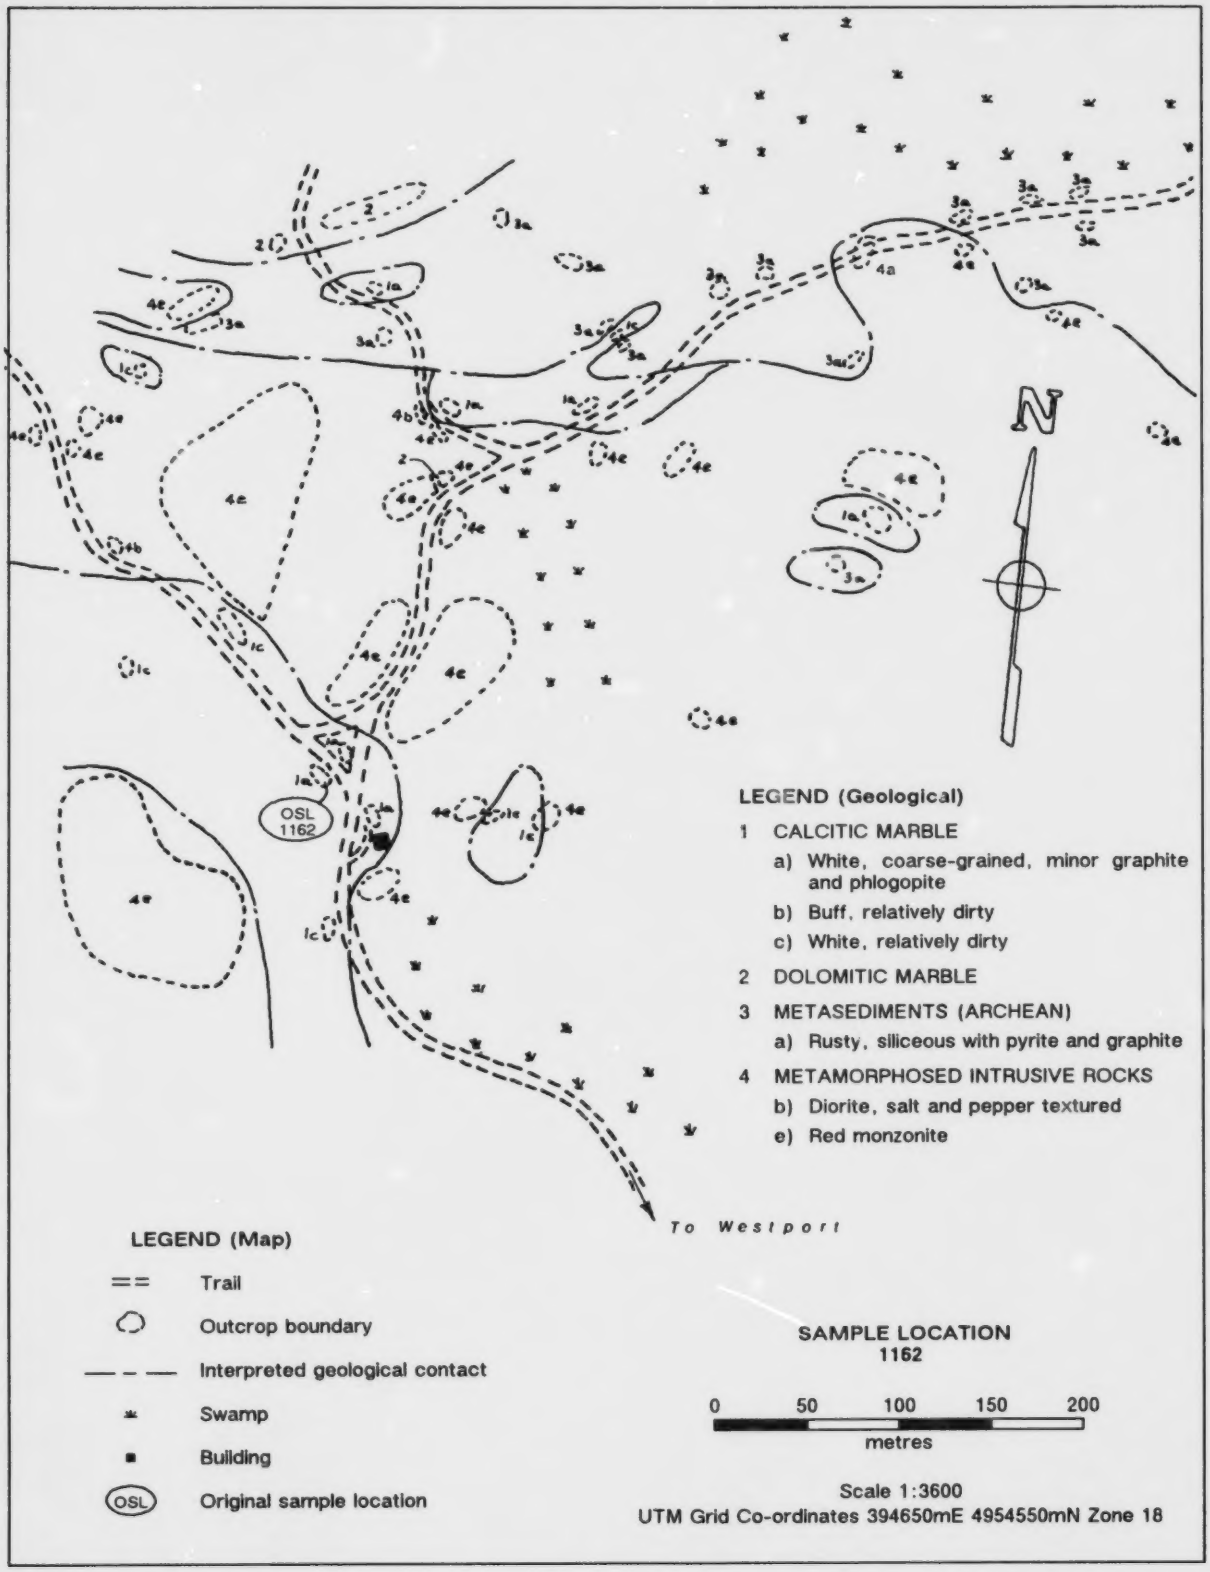

Figure 68. *Location Map, Sample 1162.*

MAP AREAS 1176, 1184, 1206, AND 1211

Location

1176—Southeast corner of South Burgess Township.

1184—Southwest corner of South Elmsley Township.

1206—On Otty Lake, North Burgess Township.

1211—North of Otty Lake, North Elmsley Township.

Map reference: NTS 31C/16.

1176—UTM 407190mE, 4957080mN, Zone 18.

1184—UTM 409900mE, 4960100mN, Zone 18.

1206—UTM 403100mE, 4965290mN, Zone 18.

1211—UTM 403000mE, 4967920mN, Zone 18.

Access

1176—On a north-trending gravel road running about 3 km west of Highway 15, off an east-trending paved road which starts at the southern end of Otter Lake, Concession VI, Lot 2.

1184—On a cottage road on the west side of Otter Lake, Concession II, Lot 29.

1206—Concession VII, Lot 2.

1211—In Maple Glen Estates, northwest of Otty Lake, Concession IV, Lot 29.

Regional Geology

The marble found in this area is part of a metasedimentary belt which occurs on both sides of Rideau Lake. Much of the belt is overlain by Paleozoic sandstone and conglomerate. The marble ranges in texture from fine to coarse grained and in colour from medium grey to white.

Local Geology

1176—This detailed map area (Figure 69) has very little marble outcrop, as the area is relatively flat. The marble is overlain by quartz sandstone of Paleozoic age, which occurs over most of the map area east of the road. The marble sampled is white with only minor impurities; however, there is only one outcrop of this marble. It is possible that the Paleozoic sandstone overlies white marble over a much larger area, but only subsurface exploration could determine this. There is minor dolomitic marble that is fine grained with nearly 5 percent impurities in the western portion of the map area.

1184—Detailed mapping of this area shows predominantly grey fine-grained marble (Figure 70). Most of this marble has a high impurity content. The marble close to the metasedimentary units tends to be brown with many small blebs of quartz throughout. Underlying the marble are calcareous metasediments, and overlying it is a thin unit of Paleozoic sandstone and conglomerate.

1206—Marble in this area is predominantly white (Figure 71) but ranges from pure white with only minor graphite and phlogopite, to impure buff with siliceous clots and bands. Some of the area is overlain by Paleozoic conglomerate which grades laterally into poorly sorted sandstone and conglomerate. Garnet-biotite paragneiss units within the marble tend to be discontinuous, trend northwest, and are normally less than 30 m wide.

1211—Marble in this detailed area is generally white (Figure 72), and grain size ranges from medium to coarse. The area is cut by granitic pegmatite veins which are up to 2 m wide. Some small units of dolomitic marble occur within the calcitic marble; however, these tend to be very thin. Overlying the area toward the northwest is Paleozoic sandstone and conglomerate.

Previous Geological Work

South Burgess and North Burgess townships have been mapped by Hewitt (1964a), and in part by Wynne-Edwards (1967) and by Wilson and Dugas (1961). South Elmsley and North Elmsley townships have been mapped by Wilson and Dugas (1961) and by Hewitt (1964a).

Chemistry

Samples 1206 and 1211 were taken from a marble unit (samples 1199 to 1213) that has relatively consistent CaO and MgO contents and a high CaO/MgO ratio. The area also has a consistently low SiO_2 content. The trace and metallic element contents are also low, with the exception of Sr. In several of the samples Sr is above 1000 ppm, but there seems to be no correlation with any other element except that the marble samples with a high Sr content are calcitic and not dolomitic.

Samples 1176 and 1184 are from a marble unit (samples 1172 to 1192) that is made up of interbedded calcitic and dolomitic marble. Two other samples from this marble unit have anomalously high metallic contents: sample 1177, a calcitic marble, has a high Sr content; and sample 1179, a dolomitic marble, has a high Cu content.

The channel sample taken at location 1206 has a high SiO_2 content and a correspondingly low CaO content. SiO_2 ranges between 1 and 5 percent in the channel samples taken at location 1211.

Reflectivity in all three samples (samples 1206z, 1211y, and 1211z) ranges from 60 to 66 percent.

Potential

Of the four areas mapped, only one yielded a poor-quality marble (sample 1184). Each of the other areas has development potential assuming that the marble is of adequate quality, although for each,

factors other than marble quality must be taken into account. For example, sample 1211 was taken from an area that has been surveyed into building lots, with a number of houses already constructed. The area from which sample 1176 was taken is overlain by Paleozoic material and will need to be drilled before the areal extent of the marble can be determined. Sample 1206 was taken from an area of predominantly clean marble with the exception of several paragneiss units within the marble.

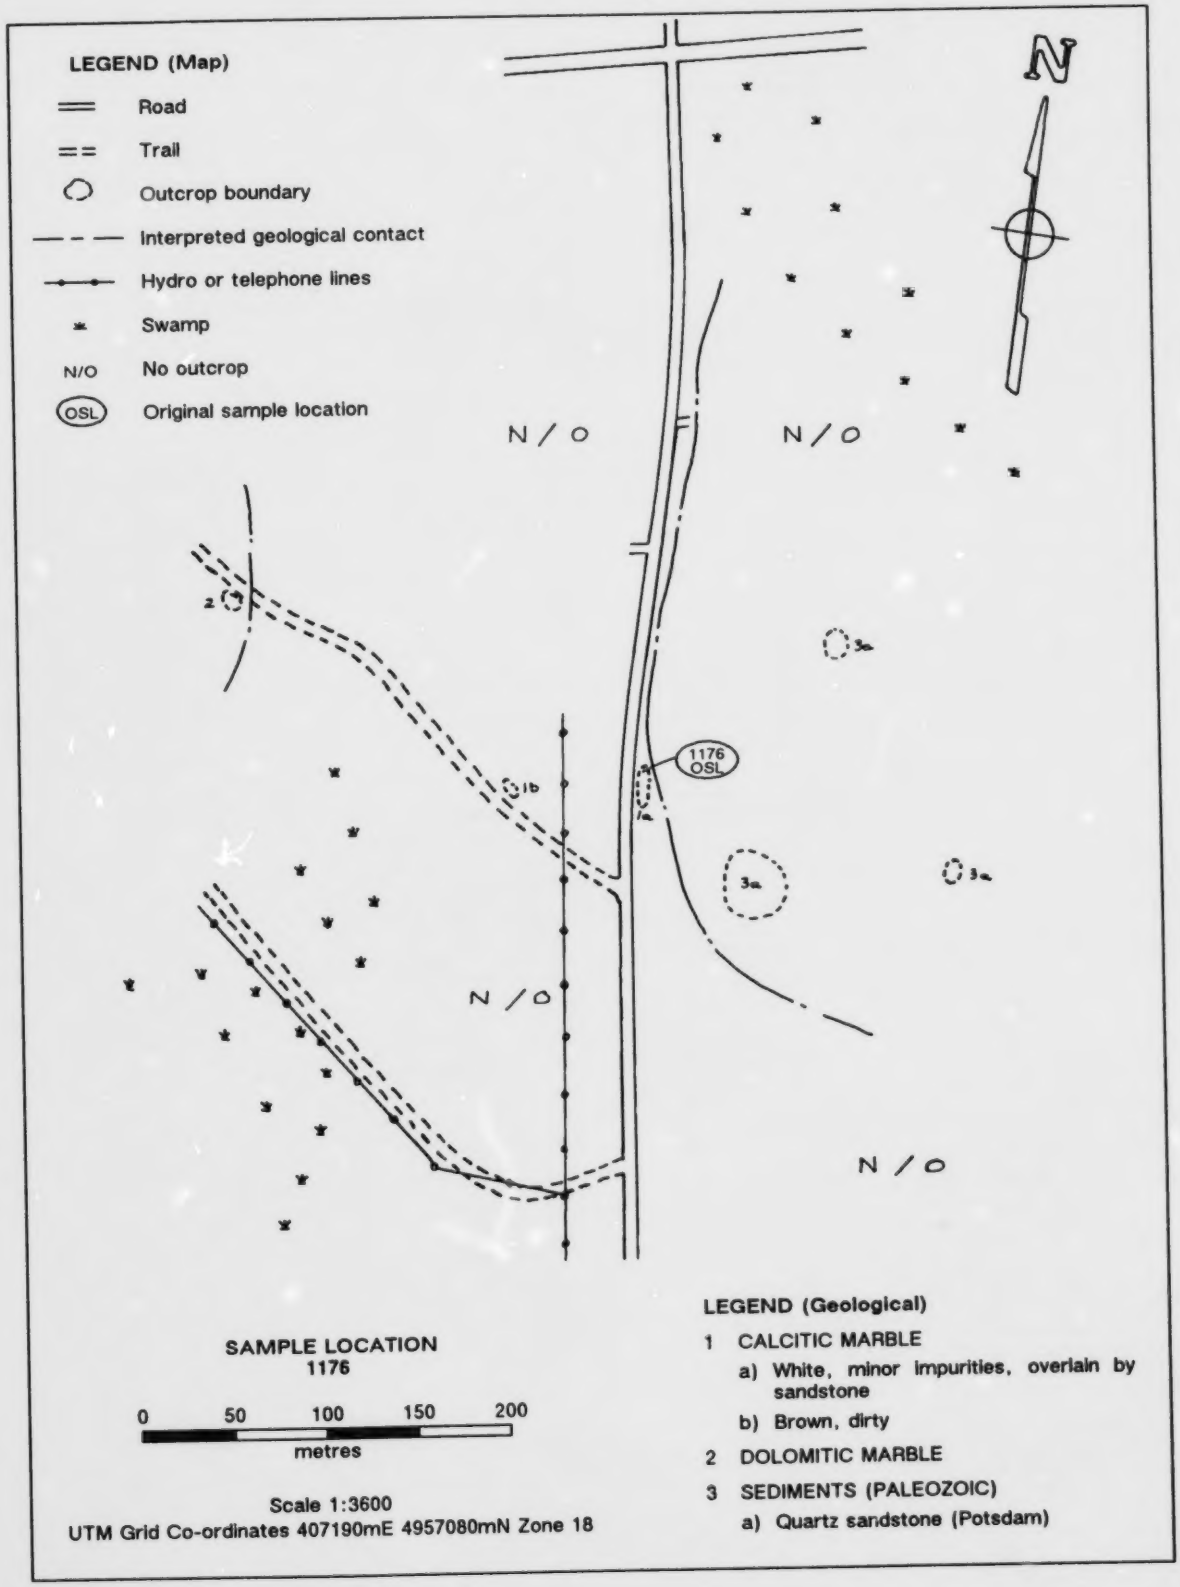

Figure 69. *Location Map, Sample 1176.*

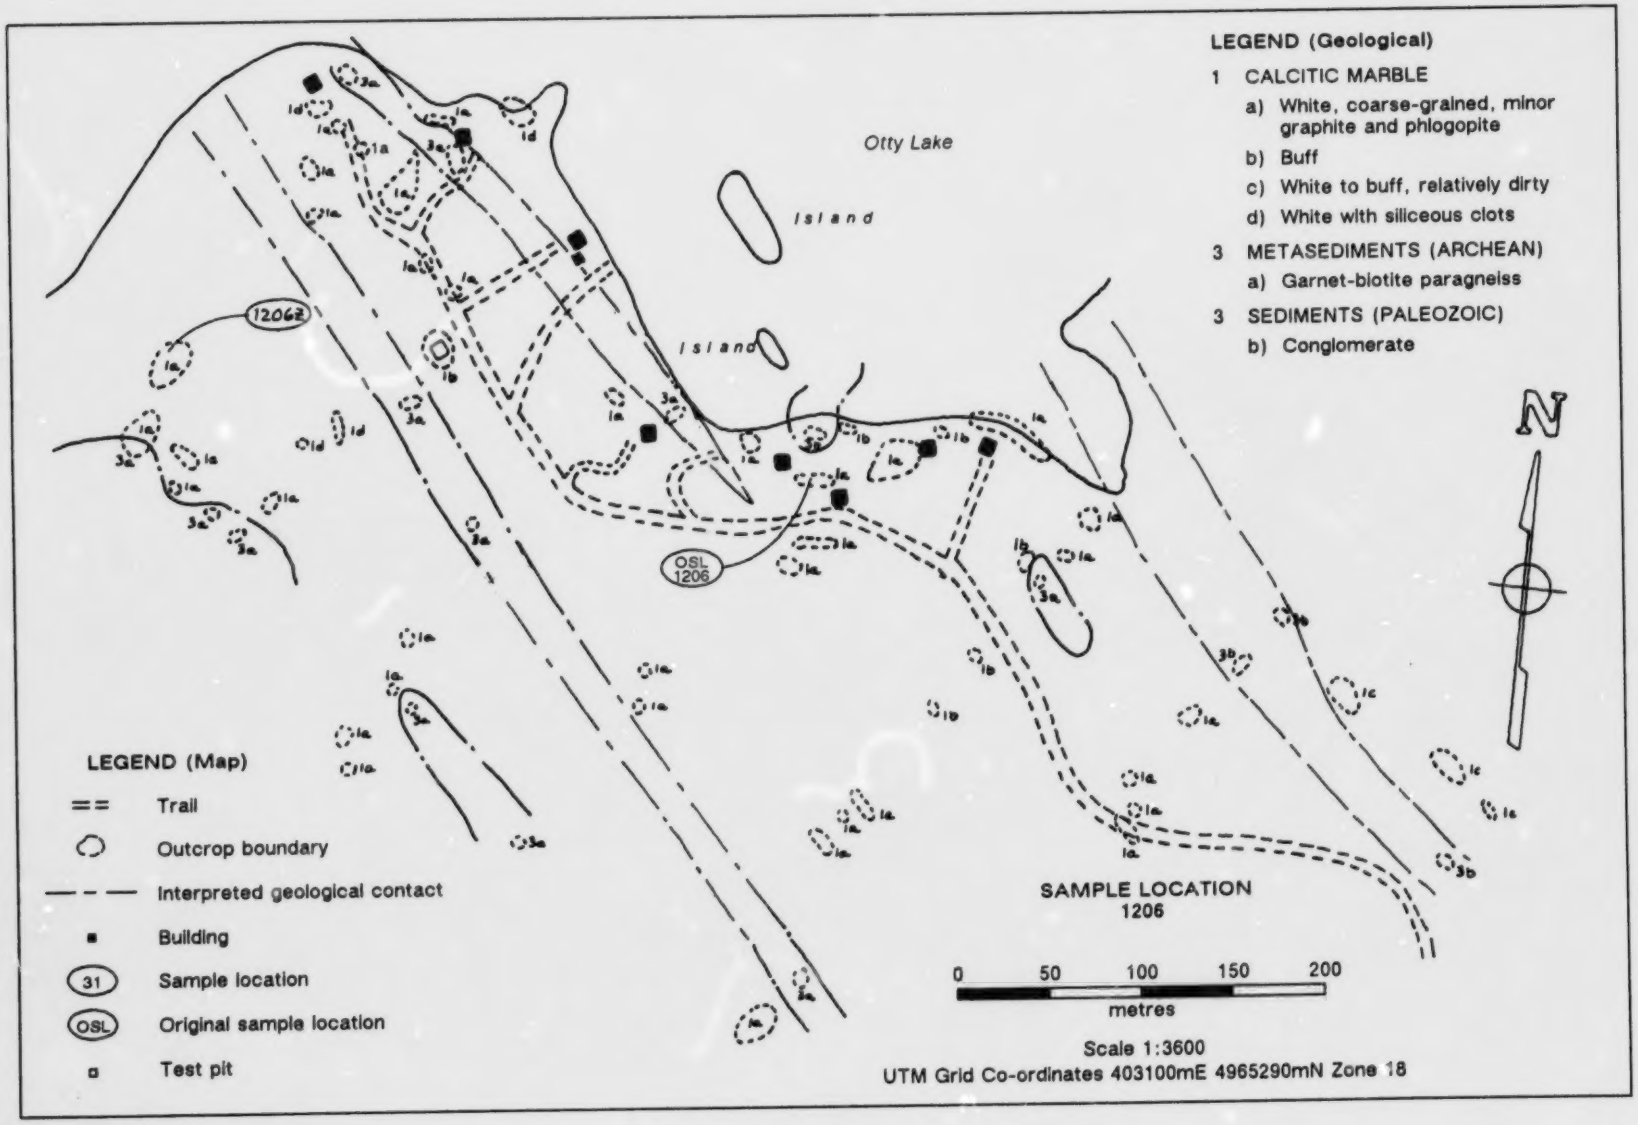

Figure 71. *Location Map, Sample 1206.*

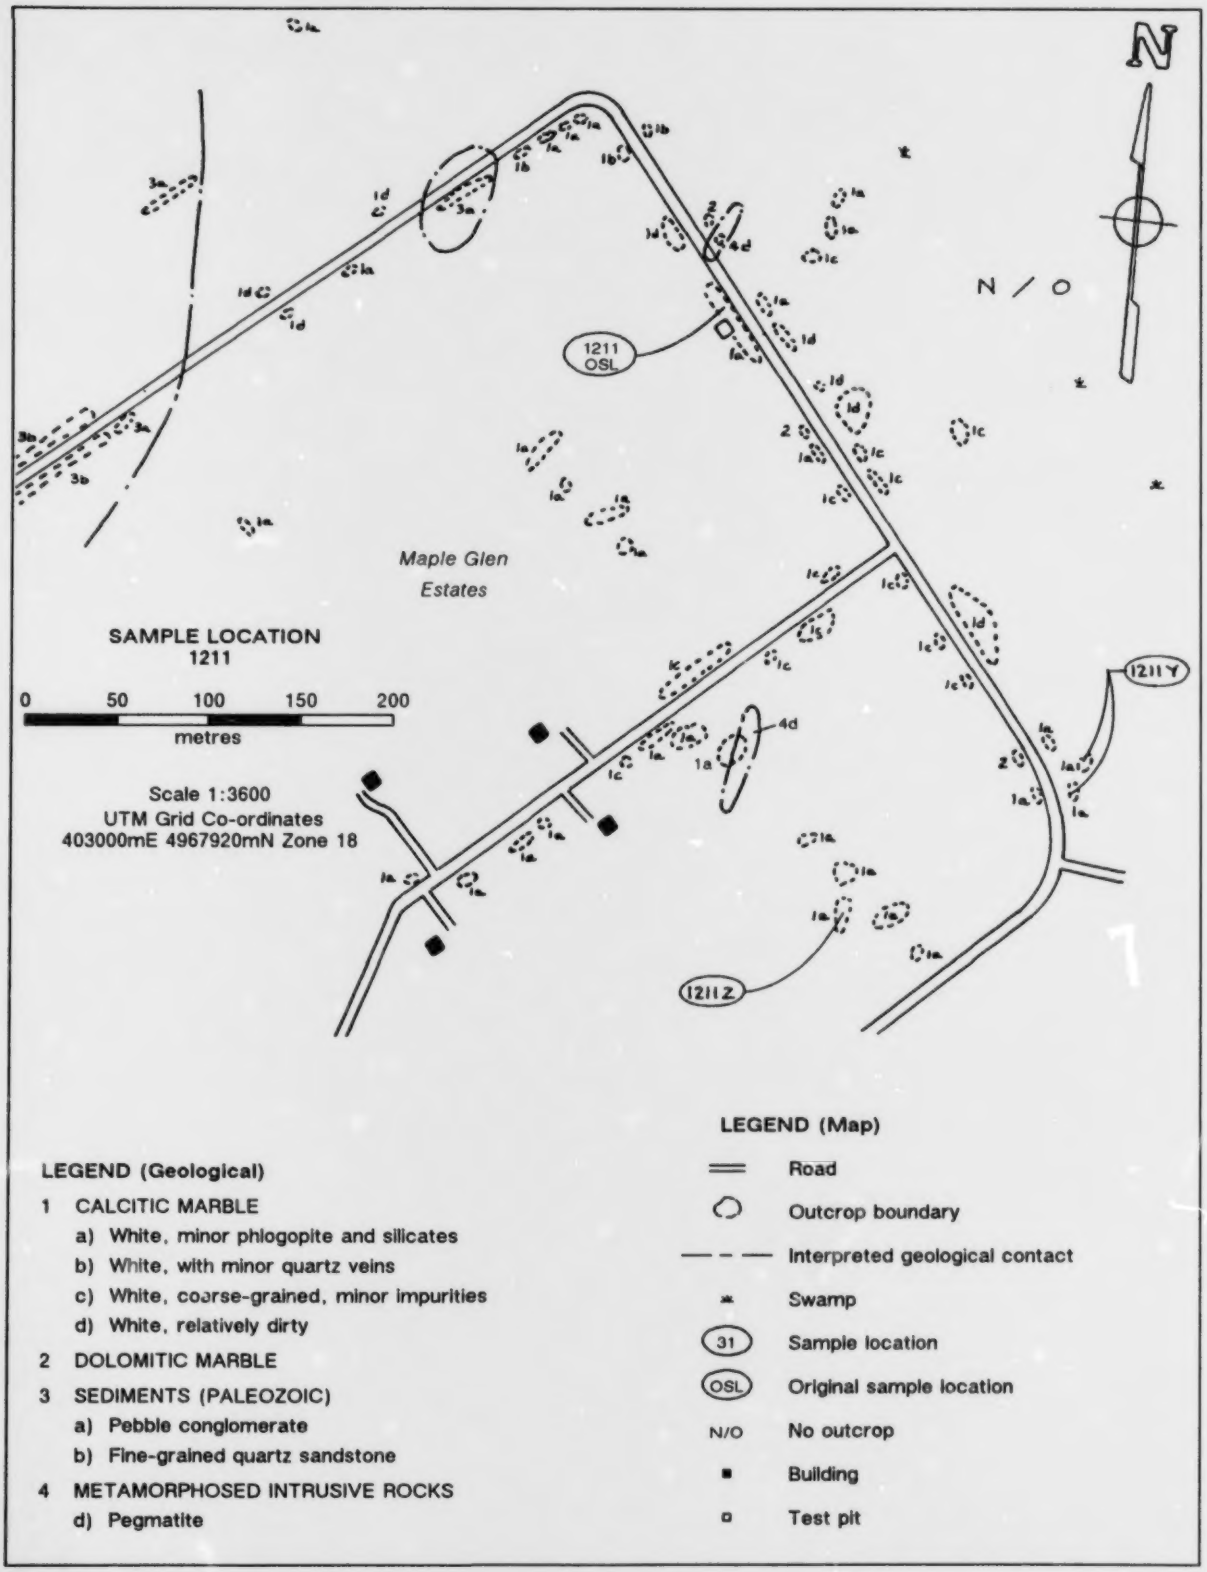

Figure 72. *Location Map, Sample 1211.*

MAP AREAS 1240/1241 AND 1249/1250

Location

All four samples were taken in west-central Bathurst Township.

Map reference: NTS 31C/16.

1240—UTM 385530mE, 4967440mN, Zone 18.

1241—UTM 384380mE, 4967180mN, Zone 18.

1249—UTM 386850mE, 4966100mN, Zone 18.

1250—UTM 385860mE, 4965250mN, Zone 18.

Access

1240/1241—1 km apart, 1.5 km west of Brooke, on Highway 7.

1249/1250—On a northeast-trending gravel road, 1 to 2 km south of Brooke.

1240—Concession VI, Lot 3.

1241—Concession VI, Lot 2.

1249—Concession V, Lot 4.

1250—Concession V, Lot 2.

Regional Geology

All four samples were taken from a stratigraphically complex marble zone which trends roughly northeast. Within and around the zone are small intrusions of granite, diorite, and syenite. Also within the marble unit are both syenite-marble and amphibolite-marble migmatites.

Local Geology

1240/1241—Within this detailed map area (Figure 73) are a number of north-trending marble units, each normally up to a maximum width of 125 m. On a large scale these units make up two distinctive migmatite units; one is a granite-marble migmatite, and the other is an amphibolite-marble migmatite. Granitic units are relatively wide (100 to 150 m), while the metasedimentary amphibolite and paragneiss units tend to be comparatively thin (50 m). Marble in the area is impure, much of it containing clots and disseminations of serpentine and diopside. Dolomitic marble occurs within a calcitic unit and is discontinuous.

1249/1250—Road outcrops indicate that the geology of this area is very similar to the geology at map area 1240/1241. Map area 1249 (Figure 74) is bounded to the northwest by granite. Marble here is coarse grained with only minor amounts of graphite and phlogopite. Marble in map area 1250 is white to orange in colour, and is bounded to the northwest by amphibolite.

Previous Geological Work

Bathurst Township has been mapped by Wilson and Dugas (1961) and Hewitt (1964a).

Chemistry

With the exception of only one or two samples, marble in this unit is highly calcitic with CaO/MgO ratios of 10 to 20 and with SiO_2 ranging from 0.3 percent to over 10 percent. All samples in this marble unit (samples 1240 to 1244 and 1248 to 1252) have low trace and metallic element contents.

Potential

The migmatitic nature of the marble and the presence of biotite, serpentine, diopside, and other impurities within it suggests that this area would yield poor-quality filler material.

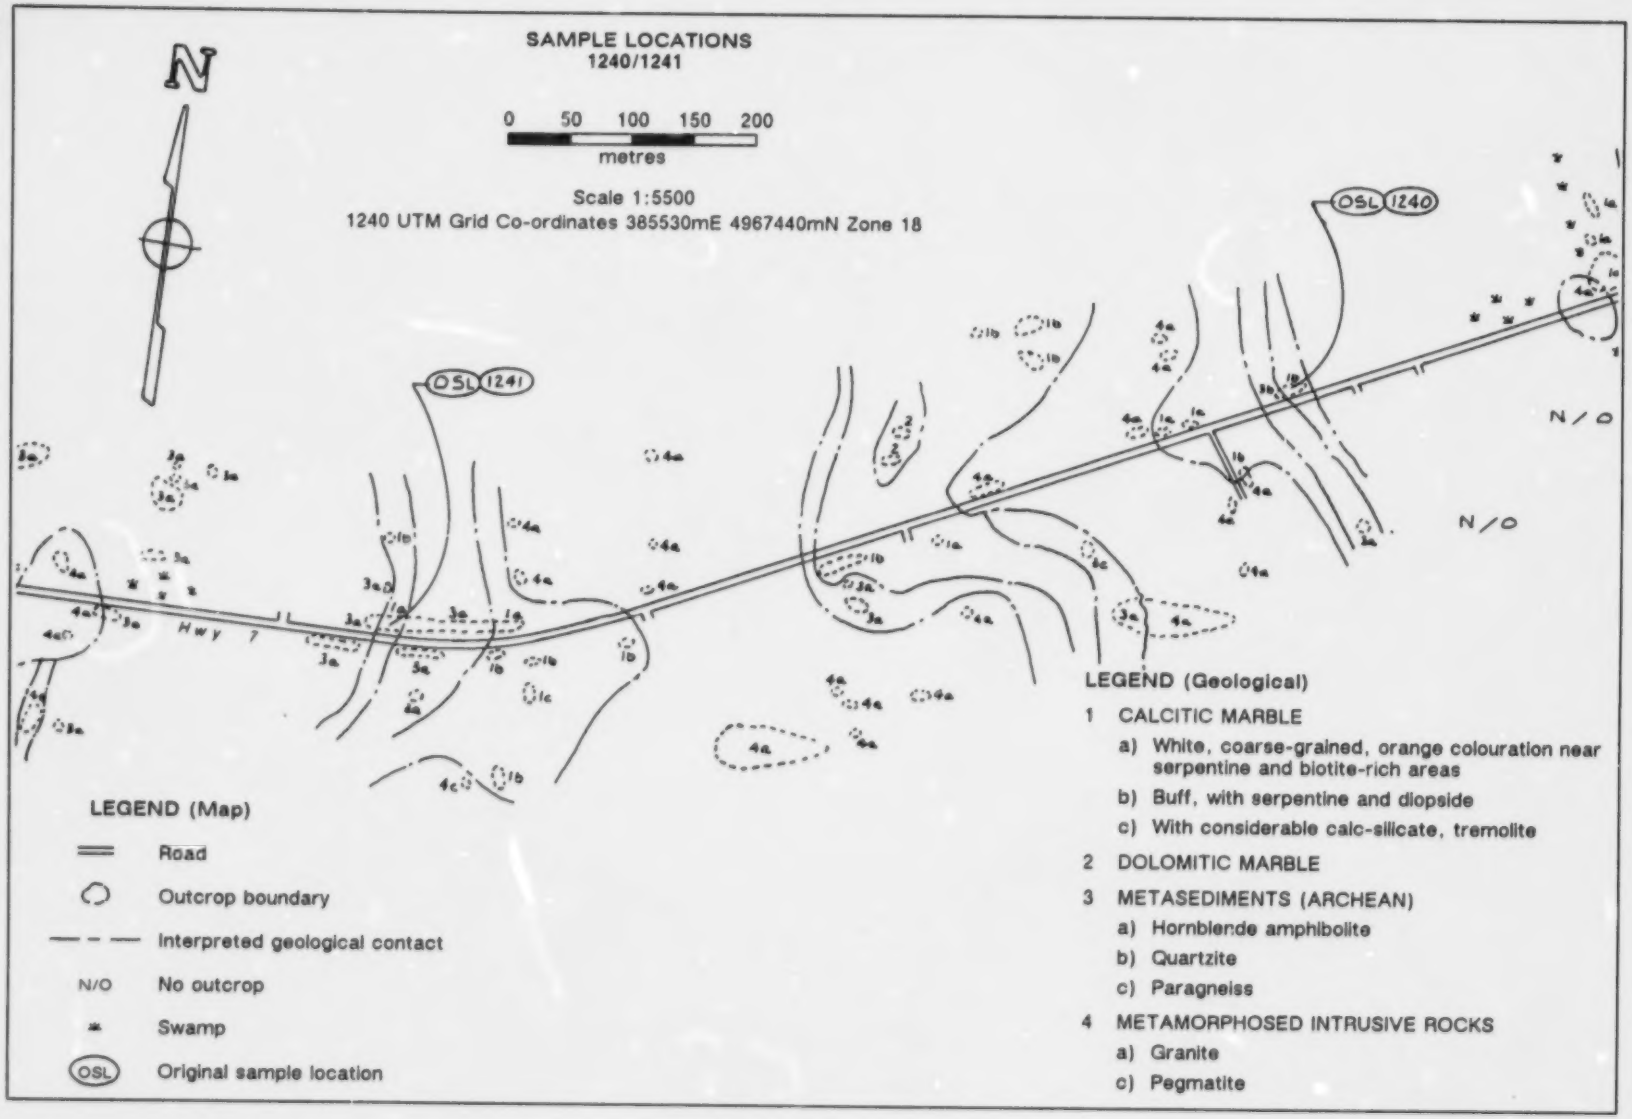

Figure 73. *Location Map, Samples 1240 and 1241.*

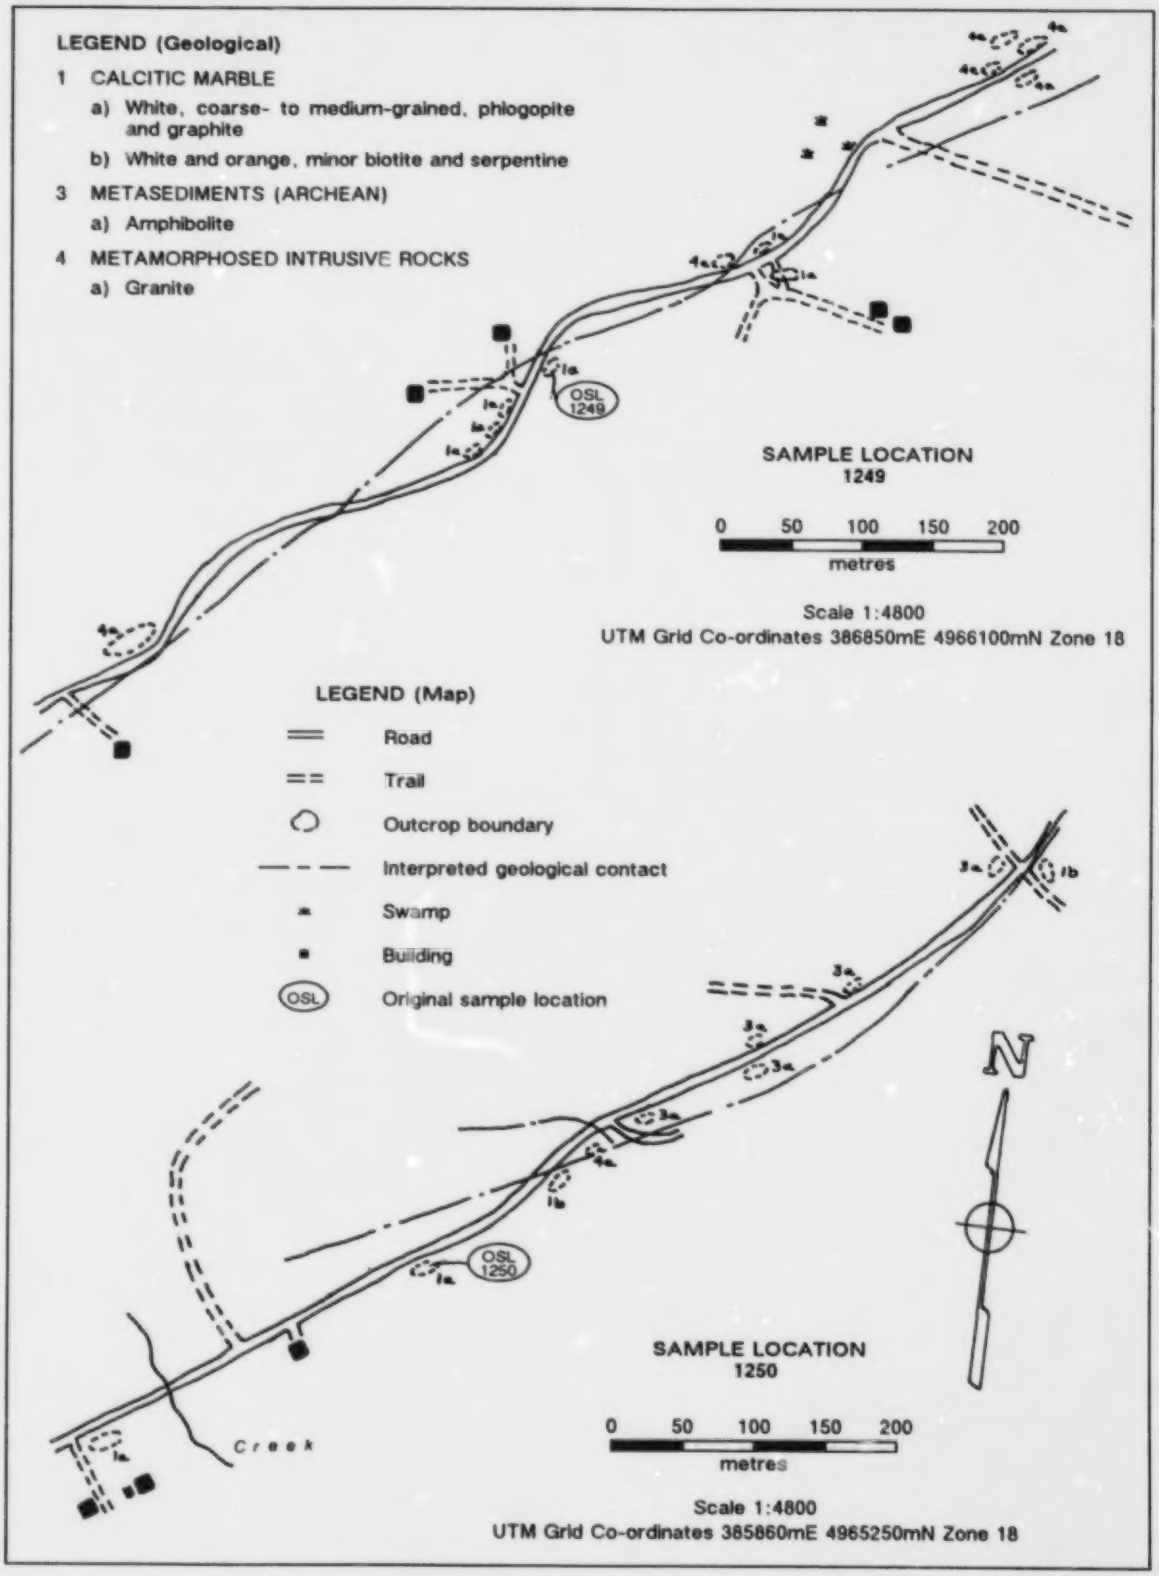

Figure 74. *Location Map, Samples 1249 and 1250.*

MAP AREA 1259

Location

Northeast corner of South Sherbrooke Township.

Map reference: NTS 31C/16; UTM 383100mE, 4958900mN, Zone 18.

Access

On a gravel road, 1 km southwest of Christie Lake, between Christie and Farrell lakes, Concession II, Lot 13.

Regional Geology

This marble belt is bounded by migmatitic rocks on both sides. The migmatites change from marble-paragneiss to syenite-paragneiss as the distance from the marble belt increases.

Local Geology

Detailed mapping of the area (Figure 75) shows that the paragneiss units are not conformable with the marble belt and are deformed, possibly during the final metamorphic episode. Marble in the area is white, containing phlogopite and graphite. Small zones of grey and white laminated marble containing graphite and phlogopite occur locally.

Previous Geological Work

South Sherbrooke Township has been mapped by Hewitt (1964a) and in part by Wilson and Dugas (1961).

Chemistry

Nearly all of the samples in this belt (samples 1259, 1276, 1277, 1284, 1285, and 1287) have high CaO/MgO ratios, averaging near 10. The MgO content ranges from 4 to 7 percent for calcitic marble, and the SiO_2 content for most of these samples is less than 1 percent. Only a few samples in this marble belt are dolomitic in composition, with one of these samples (sample 1281, Appendix A) containing anomalously high Cu and Zn contents. The other samples in this area have low trace and metallic element contents.

Potential

Marble in this belt is clean and calcitic, but the presence of silicate segregations may make the marble unusable. It is likely, however, that zones exist where these silicate segregations do not occur, making the marble much more suitable as filler-type material.

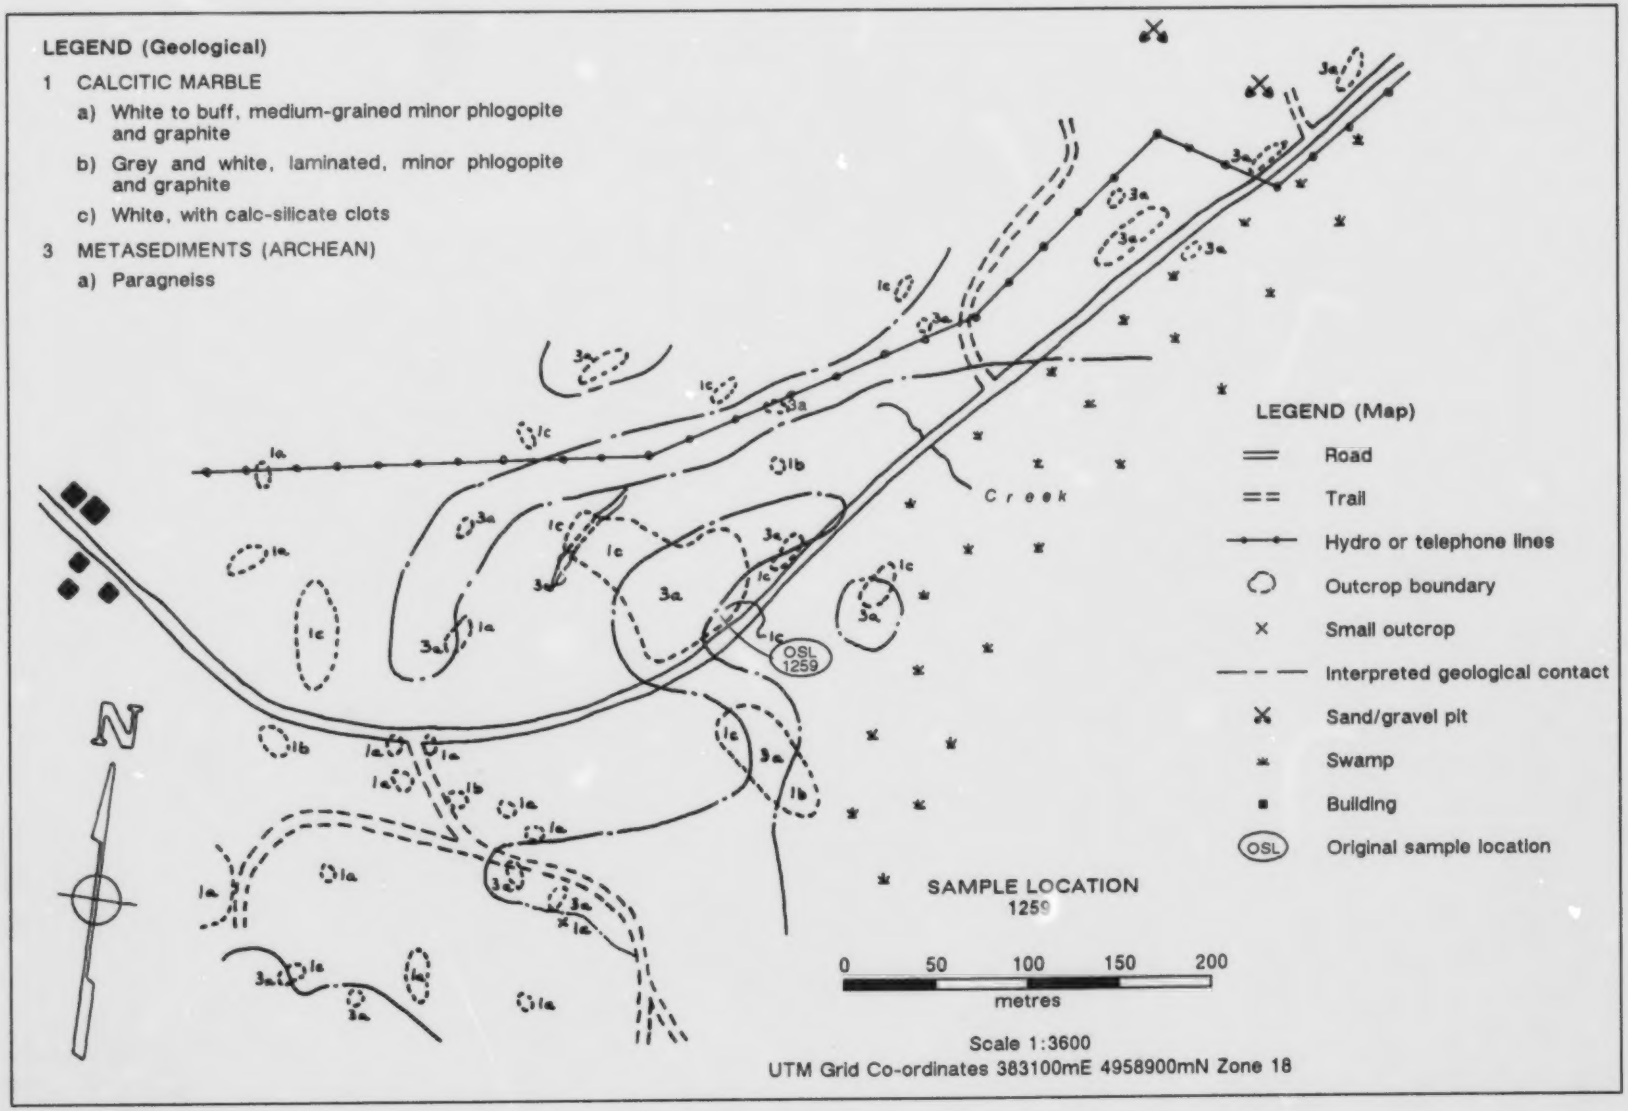

Figure 75. *Location Map, Sample 1259.*

MAP AREAS 1530, 1704, AND 1716

Location

1530—Northeast Lanark Township.

1704, 1716—South-central Darling Township.

Map reference: NTS 31F/1.

1530—UTM 384110mE, 4995970mN, Zone 18.

1704—UTM 384250mE, 5002940mN, Zone 18.

1716—UTM 385600mE, 5002600mN, Zone 18.

Access

1530—1 km southwest of Cedardale.

1704, 1716—Both samples are 1 to 1.5 km northeast of Tatlock.

1530—Concession III, Lot 23.

1704—Concession VI, Lot 6.

1716—Concession VII, Lot 4.

Regional Geology

These samples were taken from an extensive marble belt running north-northeast through Lanark Township. Within the marble belt are several metadiorite, metagabbro, and metasedimentary units. Adjacent to the marbel is a unit consisting of amphibolite and garnet amphibolite. Marble throughout the belt is predominantly grey and fine grained, and a number of tremolitic and dolomitic beds occur locally. The overall width of the belt increases toward the northwest. There are several intrusive sills within this area.

Local Geology

1530—Marble within this detailed map area (Figure 76) occurs as a 100 to 300 m wide unit, which widens toward the southwest. Paragneiss units flank the marble belt on both sides; paragneiss pods also occur within the marble. Dolomitic units occur at the margins of, and as beds within, the calcitic marble. Most of the marble in this area is coarse grained and white, with only minor graphite and silicate minerals.

1704—The marble belt in this area (Figure 77) is irregular in shape, ranging in width from 100 to 300 m. Marble also occurs as smaller pods and bands within amphibolite units outside of the main marble belt. Most of the marble is grey with only minor impurities, although there are some zones with a relatively high amphibole content.

1716—This section of the large marble belt (Figure 78) is made up of interbedded amphibolite and marble. Discontinuous units of schist and paragneiss occur within the amphibolite. Marble is predominantly light grey, much of it containing very minor impurities.

Previous Geological Work

Lanark Township has been mapped by Reinhardt *et al.* (1973). Darling Township has been mapped by Peach (1958), and in part by Goudge (1938) and Reinhardt *et al.* (1973).

Chemistry

There were many samples taken from this marble belt (samples 1500 to 1665 and 1691 to 1727); the marble is apparently chemically homogeneous throughout the area. The marbles tend to be either calcitic (with a CaO content near 50 percent and an MgO content of 5 percent) or dolomitic (CaO~30 percent, MgO~20 percent), but rarely is there an intermediate between the two end members. All samples contain low trace and metallic element contents except for sample 1525b (Appendix A), which is a dolomitic marble containing 19 percent Zn. This was a high-grade sample taken from a known zinc occurrence. The two channel samples from map area 1704 (samples 1704y and 1704z) yield reflectivities of 72 and 61 percent, respectively. Sample 1704y has a dolomitic marble composition with a very low SiO_2 content.

Potential

The grey colour of the marble and the presence of amphibolite and metasedimentary units as pods and layers within the marble belt suggests that this portion of the marble belt does not have filler potential. Sample 1530 is from a narrow zone of marble which shows the greatest potential and which seems to widen toward the southwest.

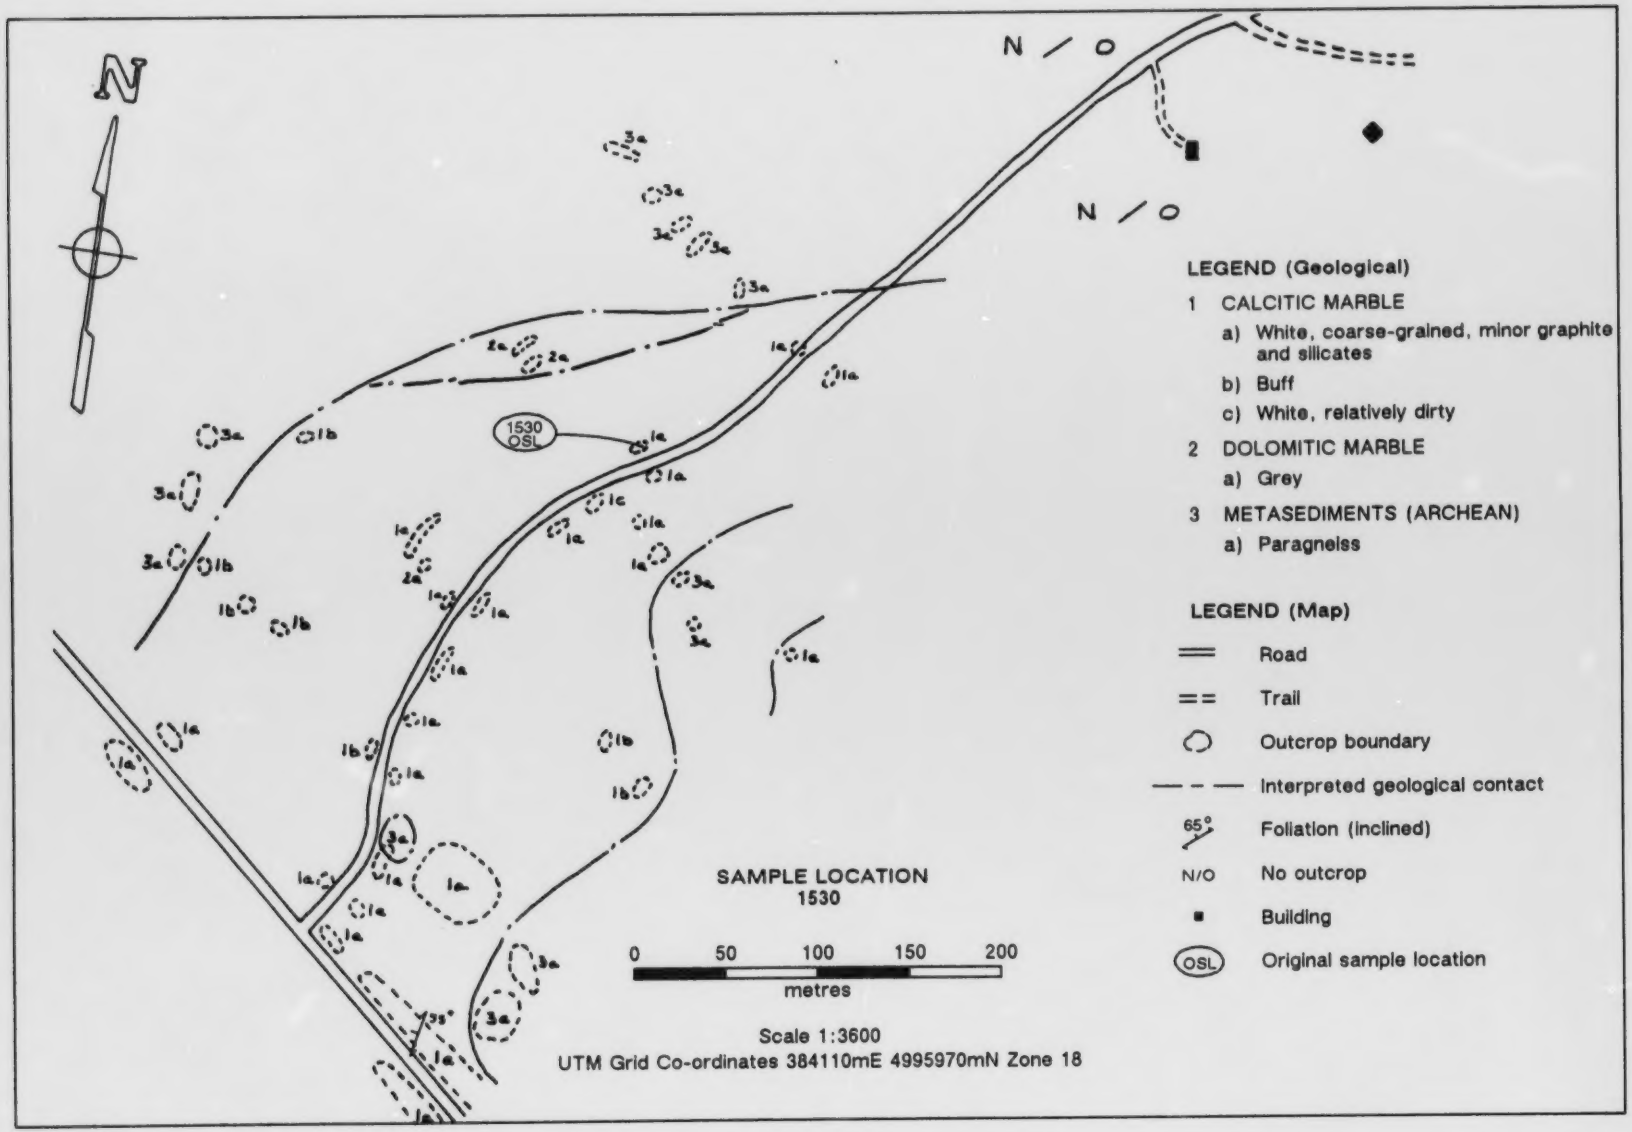

Figure 76. *Location Map, Sample 1530.*

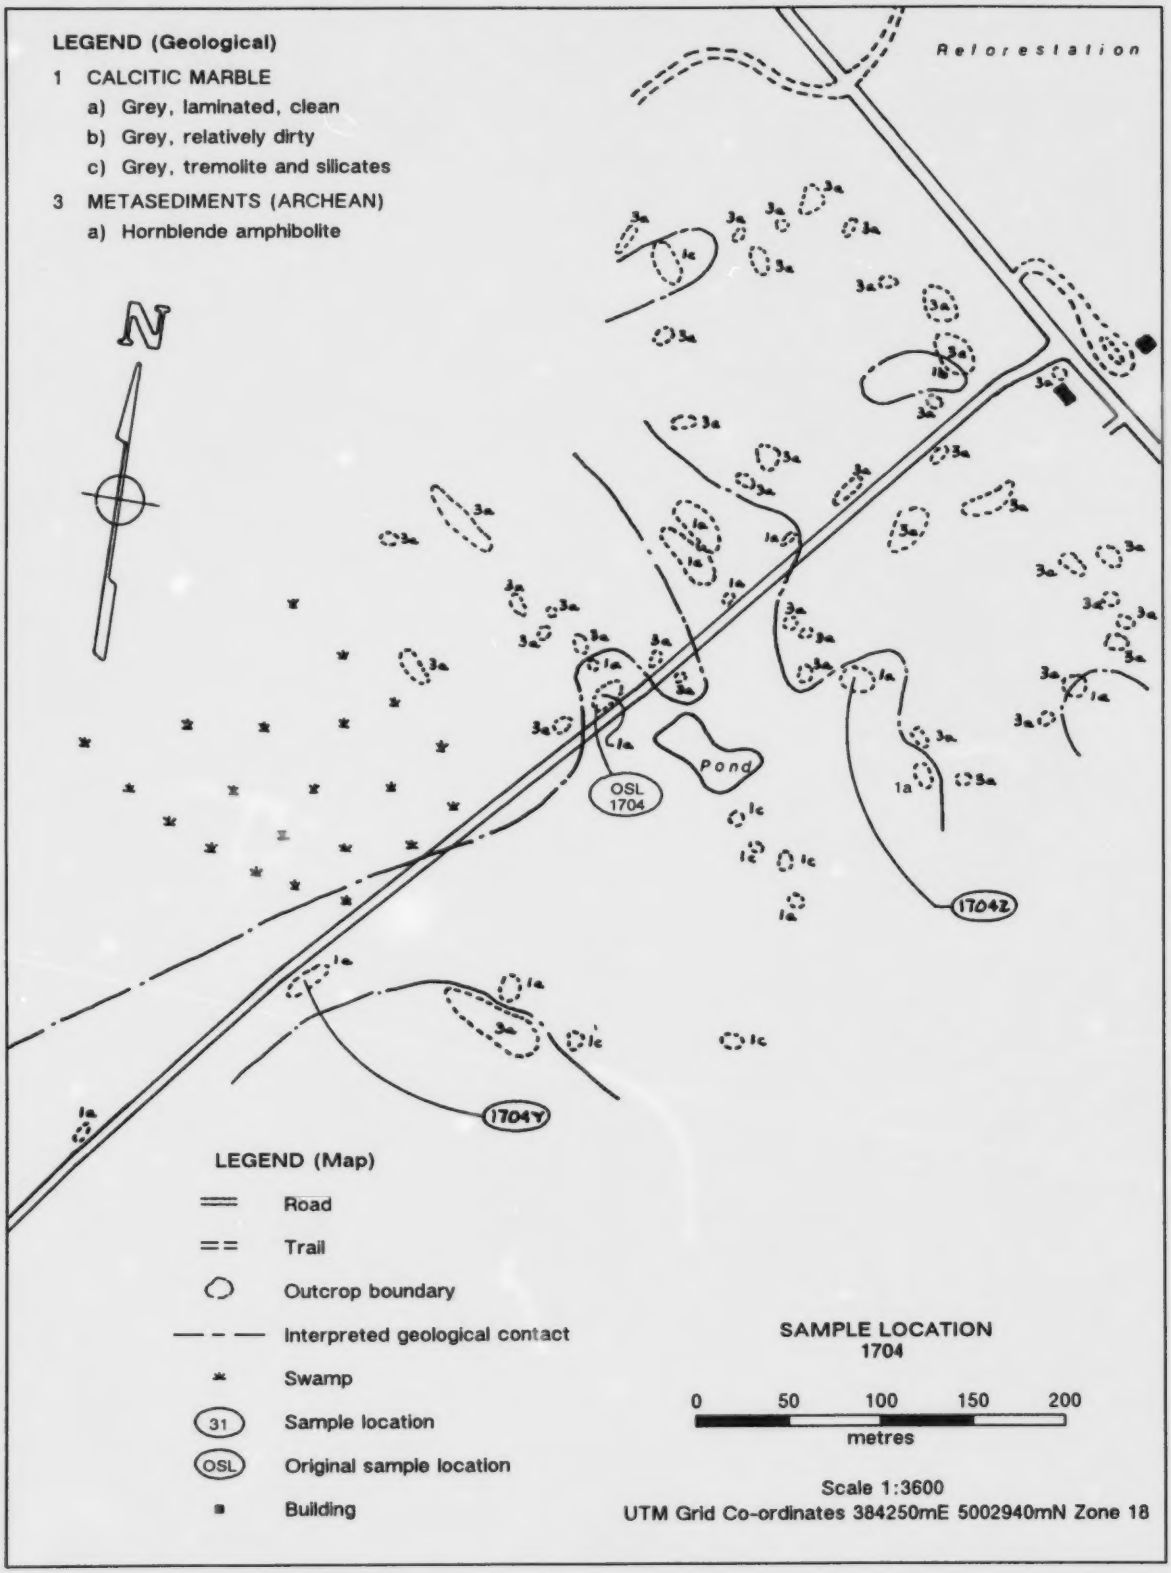

Figure 77. *Location Map, Sample 1704.*

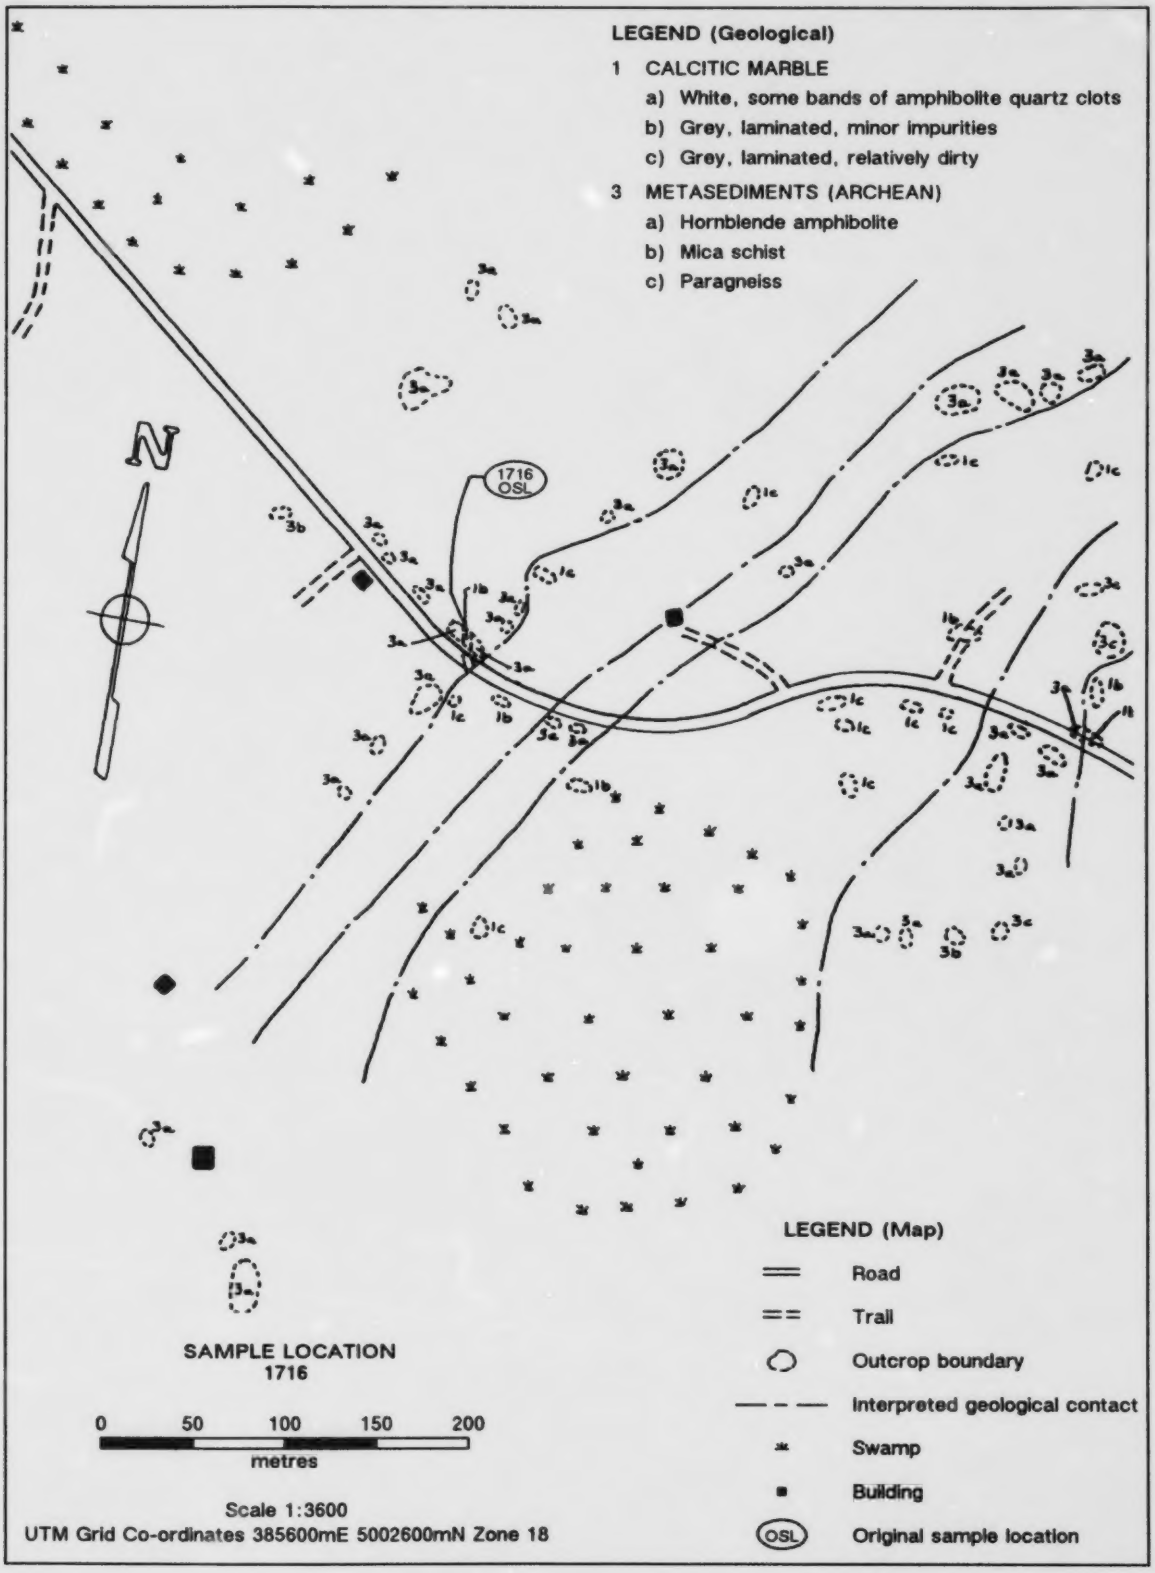

Figure 78. *Location Map, Sample 1716.*

MAP AREAS 1563, 1575, AND 1763/1764/1767

Location

1563, 1575—Northeast Lanark Township.

1764—West-central Ramsay Township.

Map reference: NTS 31F/1.

1563—UTM 390900mE, 5001630mN, Zone 18.

1575—UTM 391970mE, 5002500mN, Zone 18.

1764—UTM 398610mE, 5001230mN, Zone 18.

Access

1563—A narrow township road, Concession X, Lot 22.

1575—A narrow township road, Concession XI, Lot 22.

1764—5 km southeast of Clayton, near the intersection of Lanark County Road 16 and Lanark County Road 9, Concession II, Lot 15.

Regional Geology

These samples were taken from the northeastern end of the large marble belt which underlies most of Lanark Township. Within the marble belt are many amphibolite (paragneiss) bands, all trending northeast along the marble belt. Marble in the belt is predominantly light grey with a medium to fine grain size.

Local Geology

1563—The geology of this detailed map area (Figure 79) consists chiefly of calcitic marble. This material is grey, with a fine grain size and only minor visible mica and amphibole. Laminations are relatively narrow (1 to 3 mm) but are pronounced due to the alternating of light and dark grey marble. Dolomitic marble occurs in the southwest of the map area and tends to be very similar in appearance to calcitic marble, except that it has weathered to a sugary-textured surface.

1575—This part of the large marble belt (Figure 80) consists entirely of fine-grained grey marble. Dolomitic marble occurs in the northern part of the map area and is interbedded there with calcitic marble. Calcitic marble is predominantly grey and laminated, with only minor mica and amphibole.

1763/1764/1767—Marble in this map area (Figure 81) tends to be coarser in grain size than marble in the previous two map areas. This medium-grained marble is generally white, with 2 to 4 cm wide, fine-grained grey bands occurring locally. The white marble contains only minor amounts of graphite and phlogopite. Silicate segregation units, which occur in many of the marble belts mapped and are found locally within the white marble unit of this map area, range in size from less than 1 m in the longest dimension to outcrops tens of metres across. This unit is generally very rich in plagioclase feldspar, and also contains quartz and minor accessory minerals.

Previous Geological Work

Lanark Township has been mapped by Reinhardt *et al.* (1973). Ramsay Township has been mapped by Reinhardt *et al.* (1973) and in part by Hill *et al.* (1974).

Chemistry

Material in this part of the marble belt (samples 1740 to 1777 and 1550 to 1581) is largely of two different compositions. Dolomitic marble generally has a CaO/MgO ratio of approximately 1.4, and calcitic marble has a CaO/MgO ratio near 10. Sample 1065 has anomalously high contents of Cr, Cu, and especially Zn. All other samples in this area have low trace and metallic element contents. Three channel samples were taken from map area 1575, and one was taken from map area 1563. All channel samples have low SiO_2 and high CaO contents. Reflectivity is in the range 60 to 71 percent.

Potential

All of the detailed map areas have high-calcium marble with a low silicate content. The area would have good potential in a market for off-white coloured filler material, or it could be used as an alternative material to limestone.

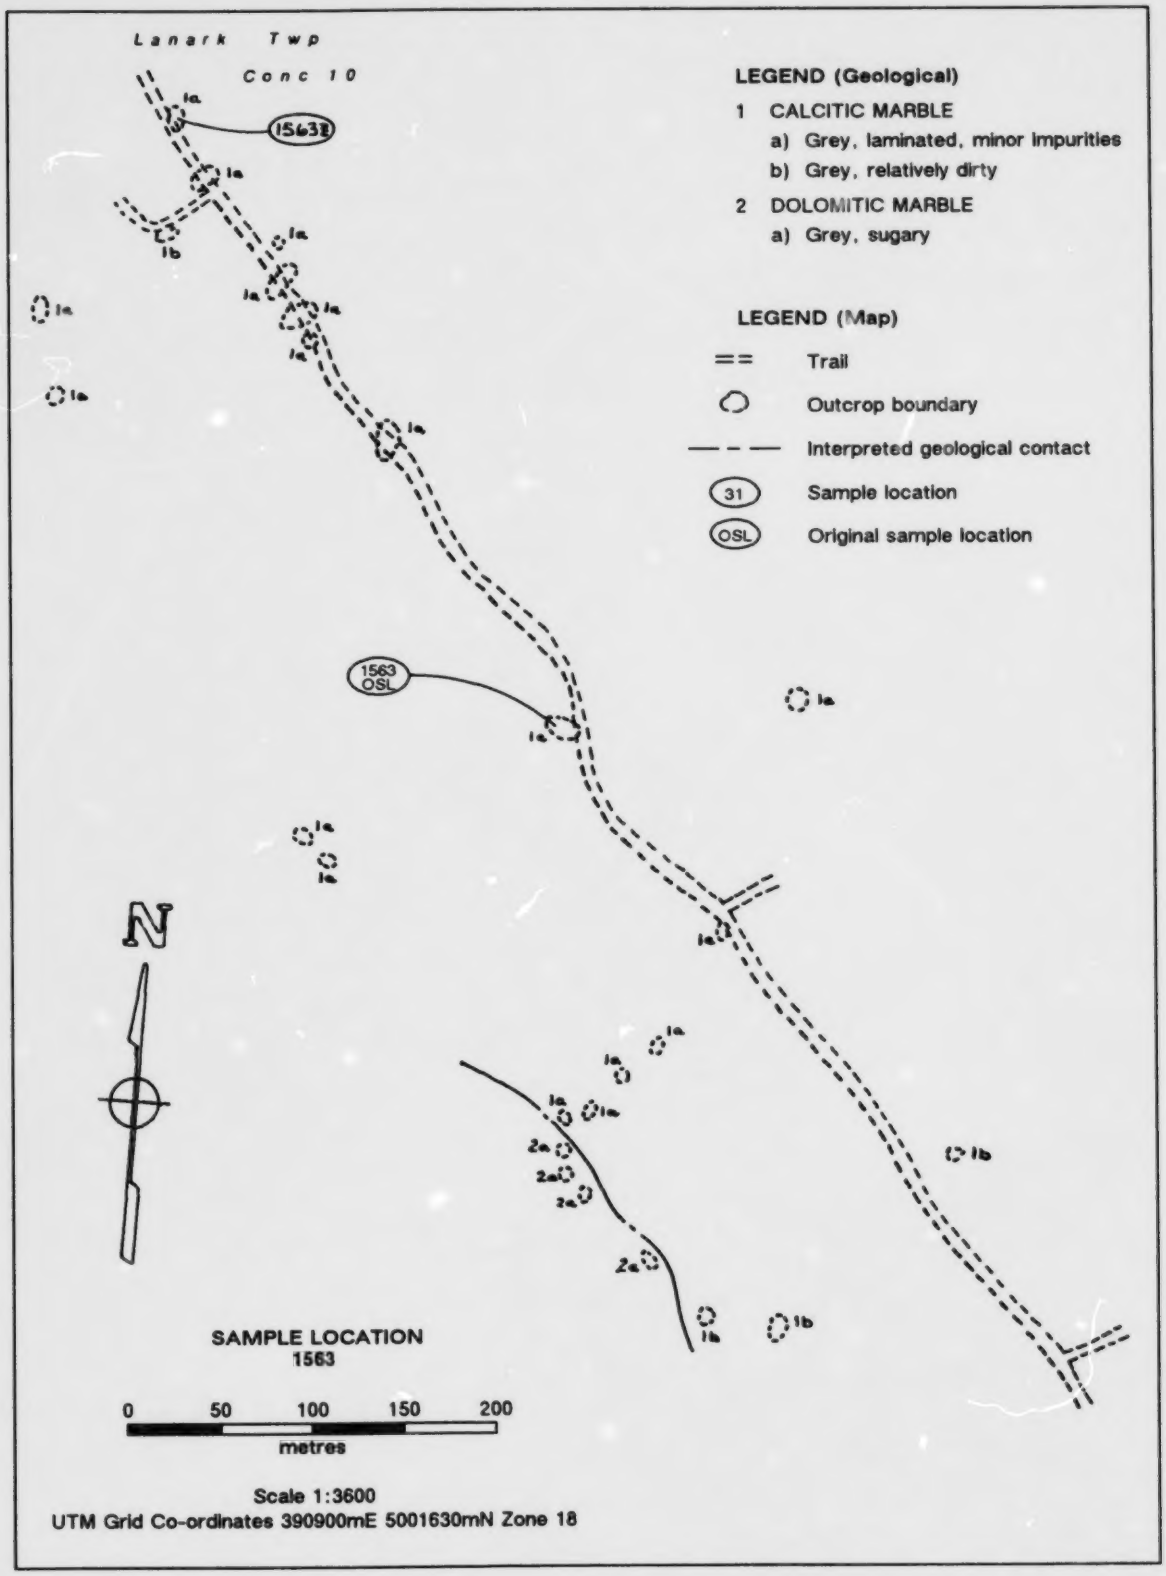

Figure 79. *Location Map, Sample 1563.*

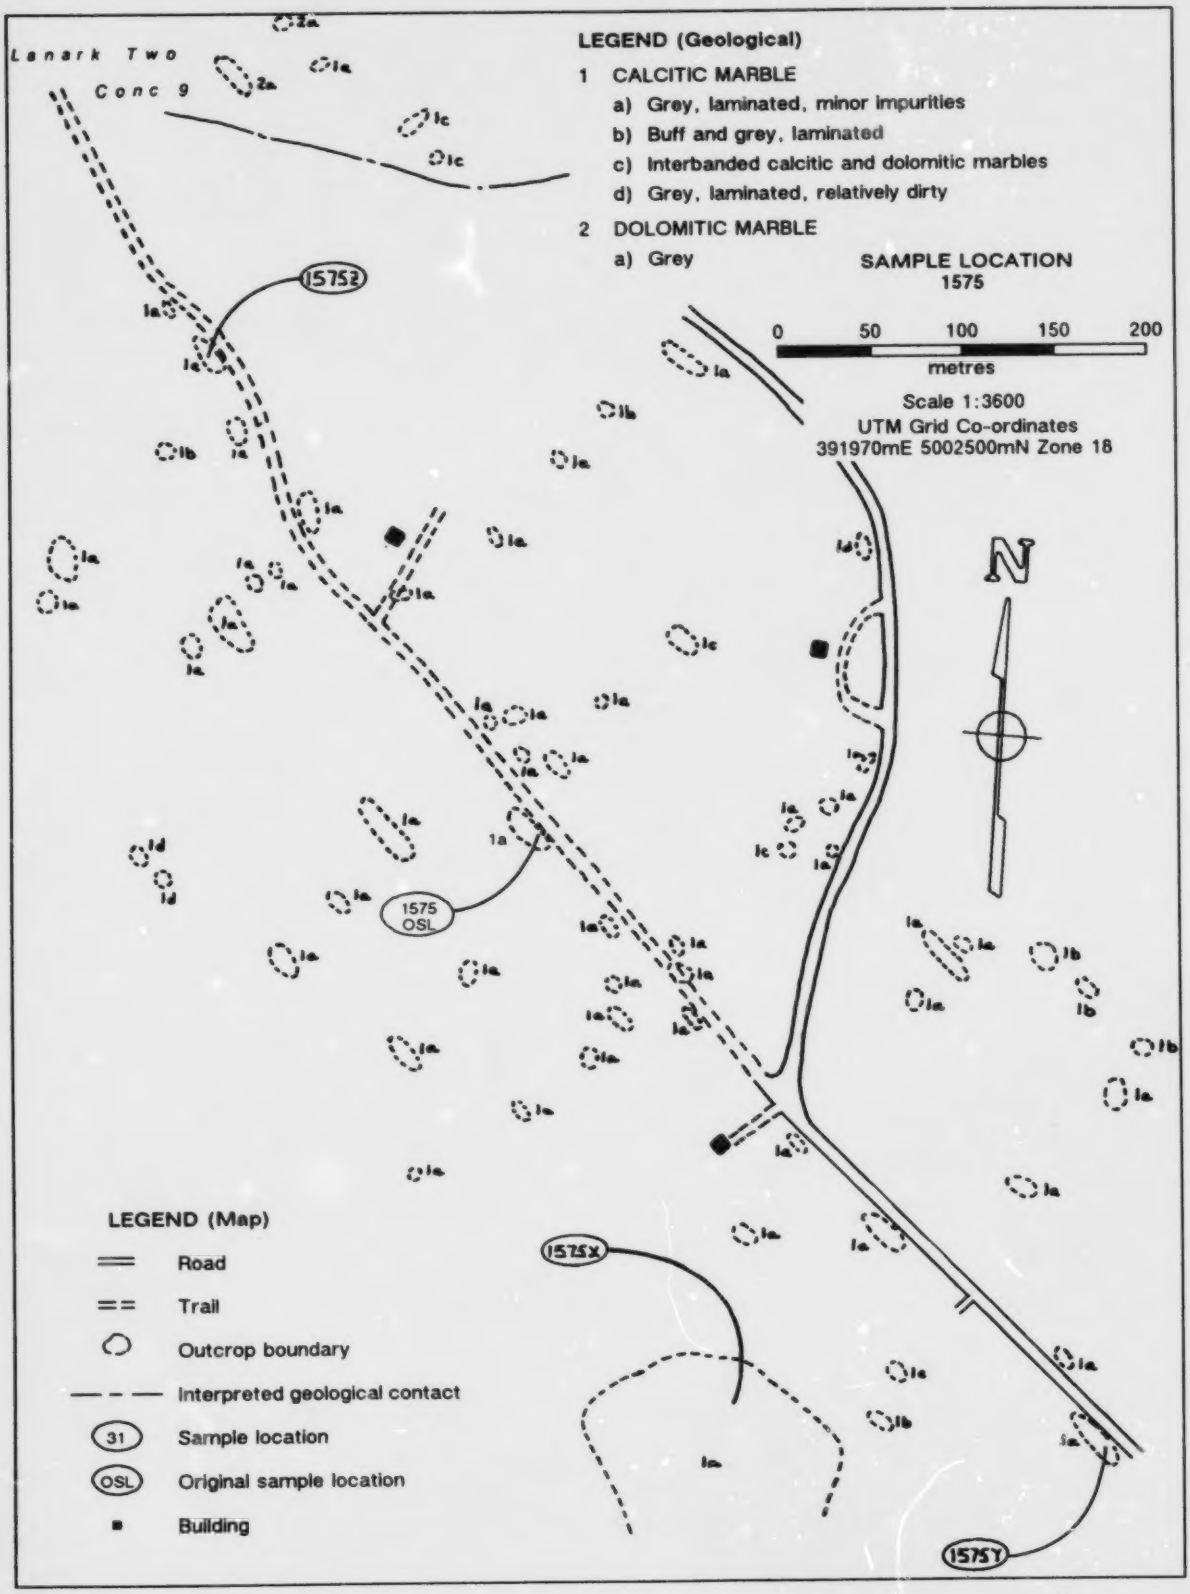

Figure 80. *Location Map, Sample 1575.*

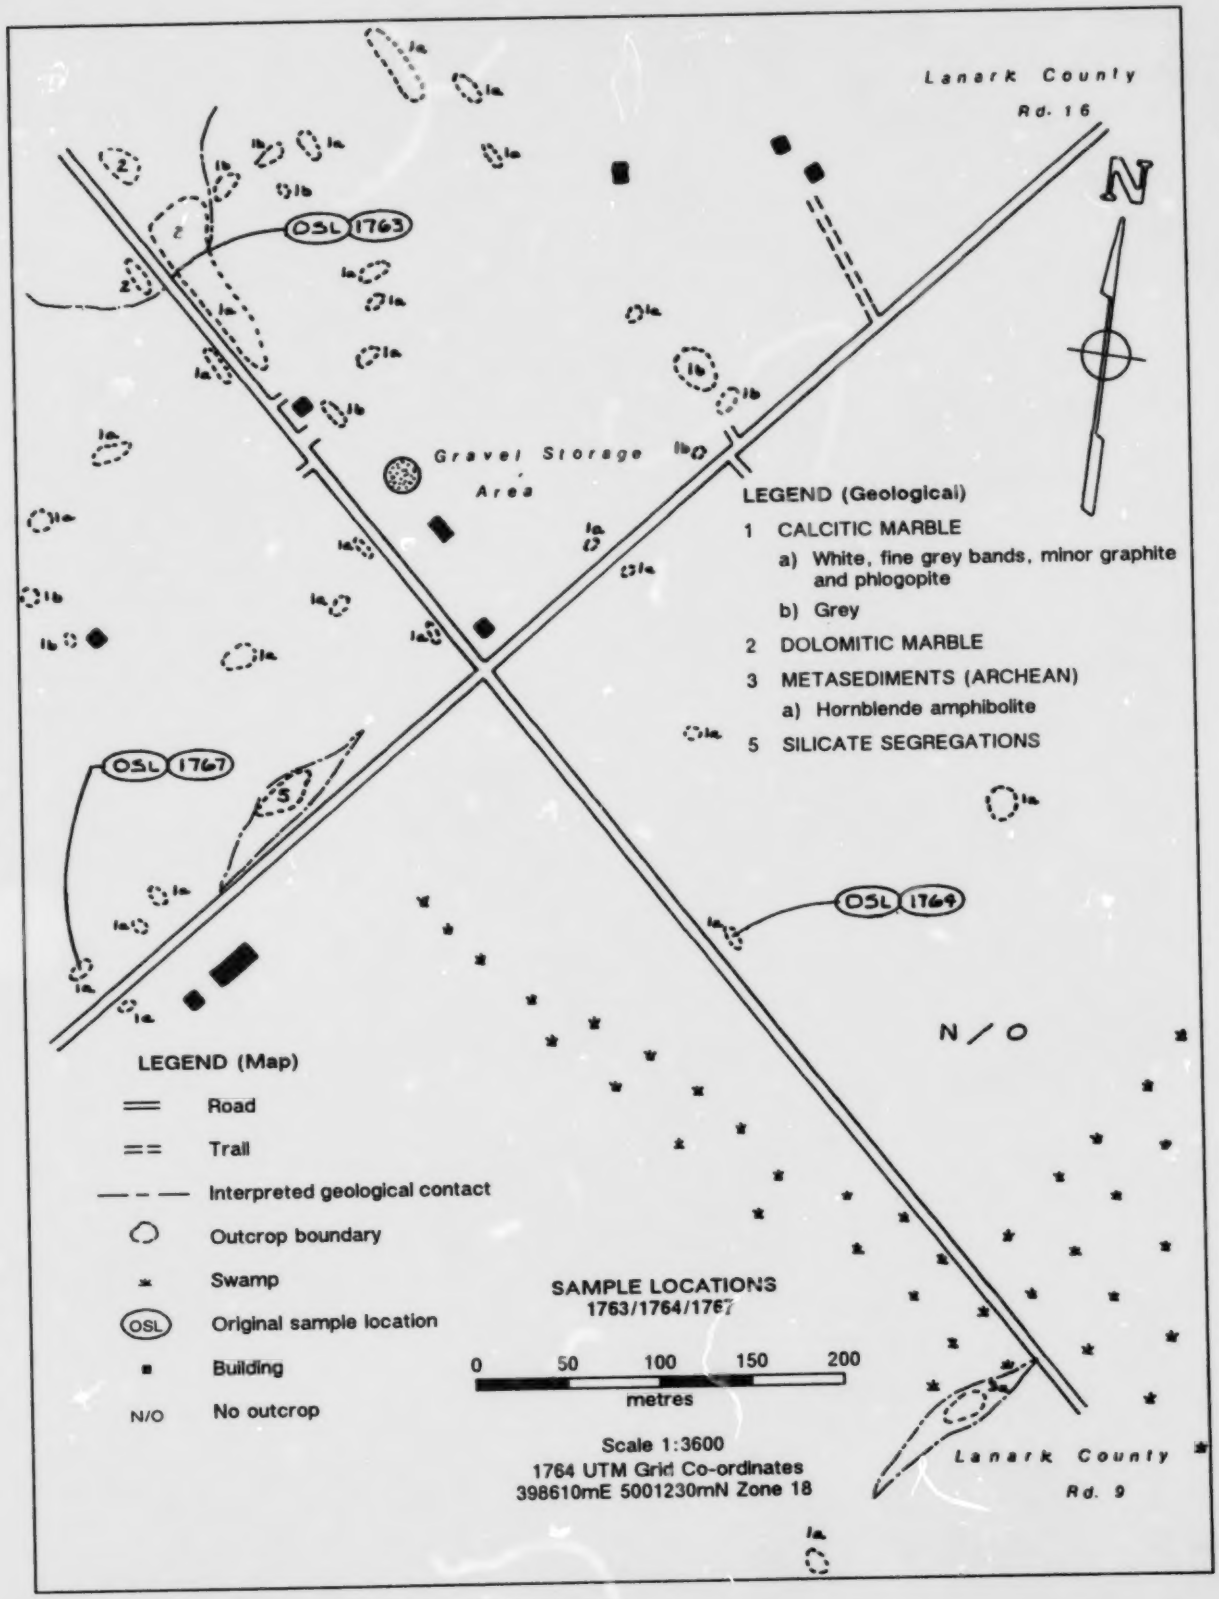

Figure 81. *Location Map, Samples 1763, 1764, and 1767.*

MAP AREA 1680

Location

Northeast Darling Township.

Map reference: NTS 31F/8; UTM 383510mE, 5013190mN, Zone 18.

Access

A gravel road, 300 m south of Lowney Lake, Concession XI, Lot 19.

Regional Geology

The marble belt from which sample 1680 was taken is bounded to the south by metavolcanics and to the north by metamorphosed granitic intrusive rocks. The marble is predominantly grey, fine grained and has been intruded by small bodies of dioritic composition.

Local Geology

Detailed mapping in the area (Figure 82) shows no intrusive rocks but only grey, and grey laminated marble of medium grain size. Impurities in the marble are minor, including pyrite, phlogopite, graphite, and locally, calc-silicate minerals. Dolomitic marble occurs as discontinuous bands in calcitic marble.

Previous Geological Work

Darling Township has been mapped by Peach (1958) and in part by Goudge (1938) and Reinhardt *et al.* (1973).

Chemistry

Most of the marble in this belt (samples 1673 to 1690 and 1824 to 1845) is dolomitic with a CaO/MgO ratio near 1.4. On a regional scale, calcitic marble appears to be restricted to narrow bands within the dolomitic material, as compared to the predominantly calcitic marble composition with minor dolomitic marble seen in the detailed map area. The SiO_2 content is low across the belt, except near the contact with the metavolcanics. The trace and metallic element contents are low throughout the belt. The two channel samples from the area have low SiO_2 and high CaO contents. Reflectivity ranges from 60 to 73 percent.

Potential

Marble is generally very pure with a predominantly grey dolomitic or calcitic composition. A market specific to these qualities or a method of beneficiating the marble to increase whiteness would be needed.

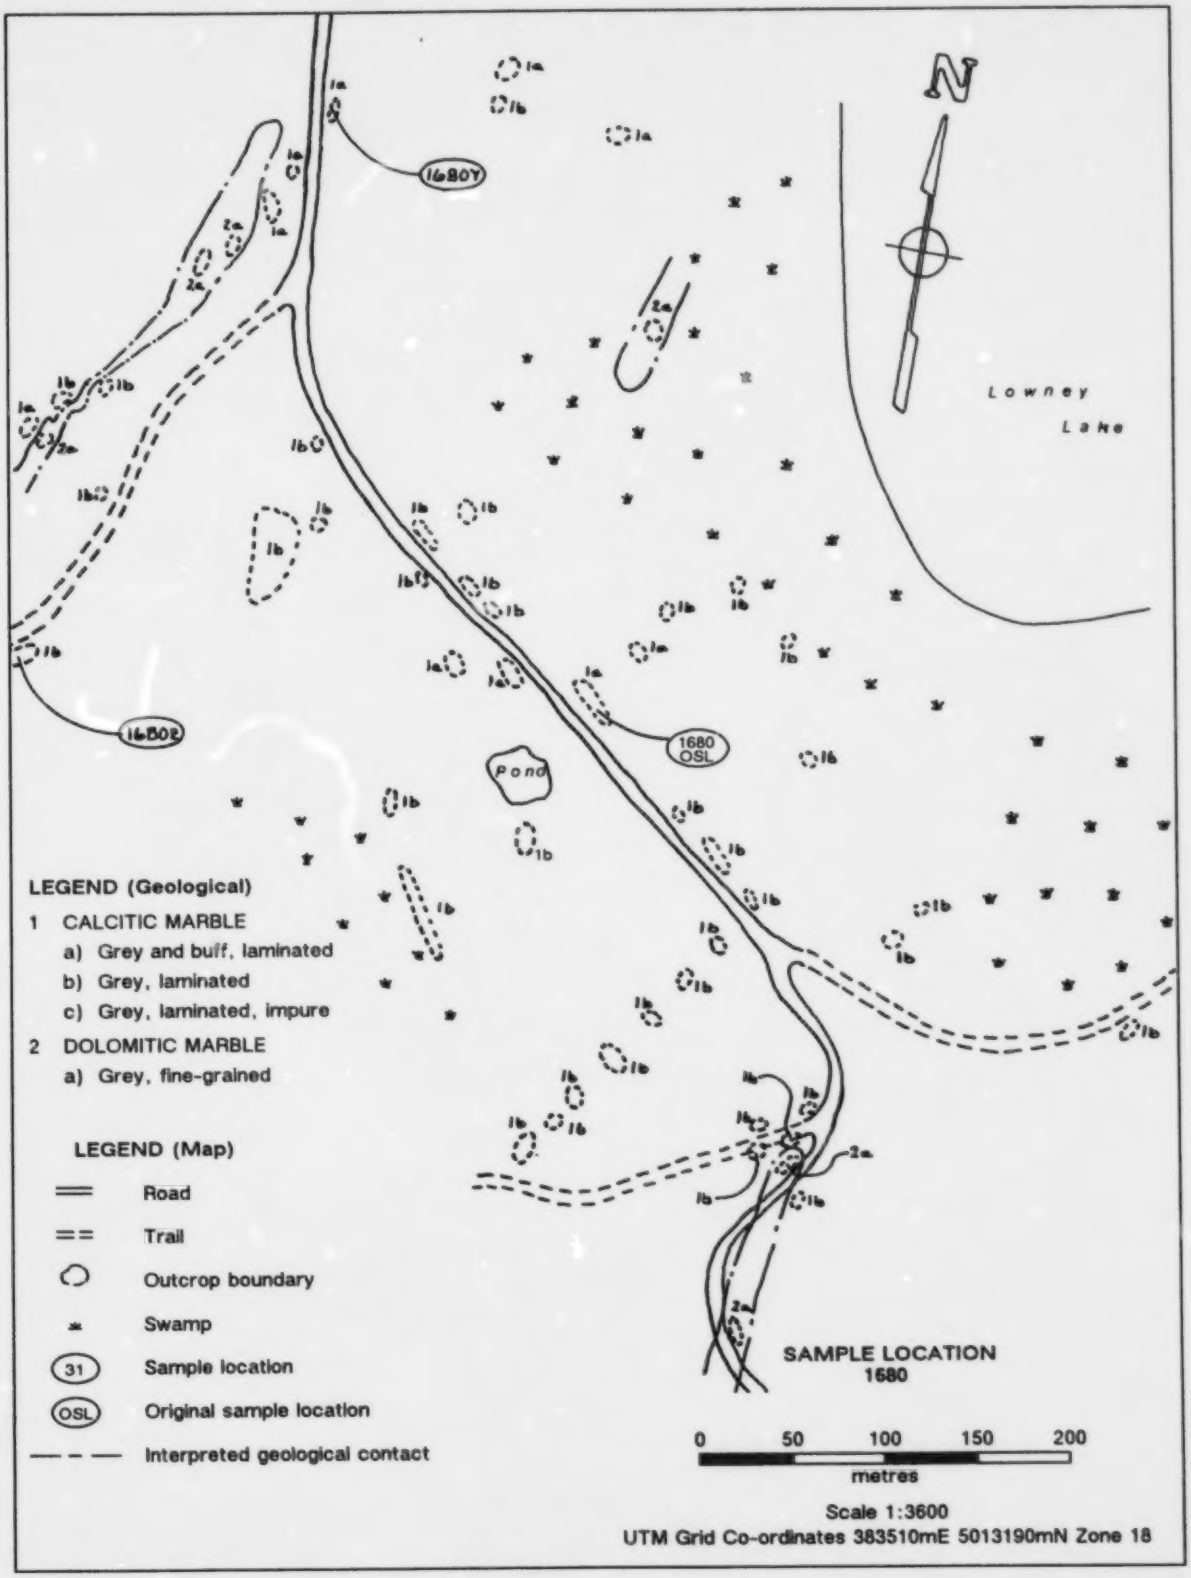

Figure 82. *Location Map, Sample 1680.*

MAP AREA 1797

Location

Central Ramsay Township.

Map reference: NTS 31F/1; UTM 404270mE, 5000760mN, Zone 18.

Access

From the former Carleton Lime Products or Bonnechere Lime Marble Quarry in south-central Ramsay Township, 1.3 km southeast of Galbraith, Concession IV, Lot 7.

Regional Geology

The marble belt from which sample 1797 was taken is just east of the large marble belt running through Lanark Township. It is separated from the main marble belt by a northeast-trending sequence of granodiorite, migmatite, and amphibolite. Within the marble belt are bands of amphibolite, which run parallel to the belt.

Local Geology

This sample was taken from an abandoned marble quarry (Figure 83). There are several small quarries or test pits surrounding the quarry which have had only limited exploration work done on them. Several thin, less than 50 m wide amphibolite units trend subparallel to the marble foliation. Most of the marble is coarse to medium grained with minor graphite, phlogopite, and muscovite.

Previous Geological Work

Ramsay Township has been mapped by Reinhardt *et al.* (1973) and in part by Hill *et al.* (1974). Short descriptions of this quarry are provided by Hewitt (1964b) and Hewitt and Vos (1972).

Chemistry

Most of the regional samples from this marble belt (samples 1778 to 1802) have low impurity contents. Trace and metallic element contents are also low in most samples (for example, sample 1797, Appendix A). The one exception is sample 1788 (Appendix A) which has a Ba content of 2880 ppm. This sample also has a high SiO_2 content.

Potential

Much of the marble has been quarried from this area, but indications are that much more good white marble is present. The marble may have to be beneficiated to remove the small quantities of graphite and mica impurities.

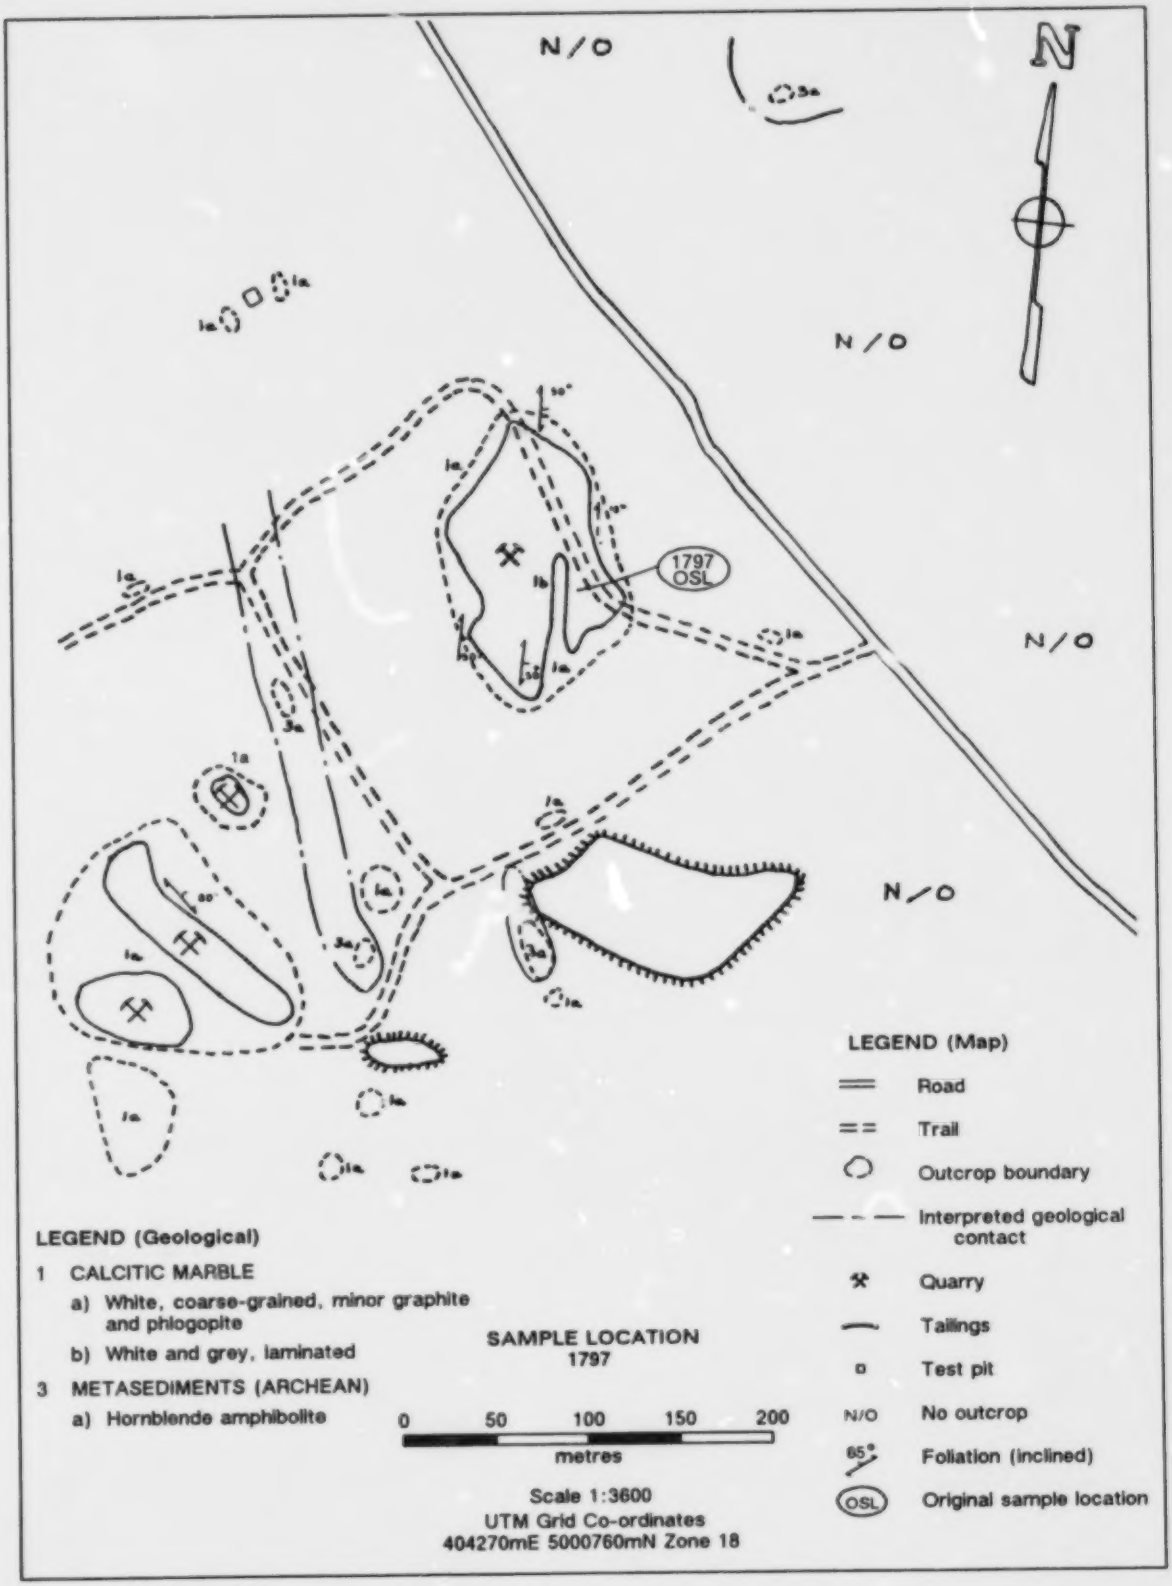

Figure 83. *Location Map, Sample 1797.*

MAP AREAS 1891/1892/1893 AND 1903

Location

All samples are from the northern corner of South Sherbrooke Township.

Map reference: NTS 31C/15.

1891—UTM 380150mE, 4968300mN, Zone 18.

1892—UTM 380050mE, 4969050mN, Zone 18.

1893—UTM 380100mE, 4969400mN, Zone 18.

1903—UTM 377850mE, 4969350mN, Zone 18.

Access

1891/1892/1893—Go east at the last intersection. All samples were taken from around the next intersection.

1903—Take the second concession road off the road through Maberly. The sample was taken at the first intersection, Concession XI, Lot 16.

1891—Concession IX, Lot 18.

1892—Concession IX, Lot 19.

1893—Concession X, Lot 19.

Regional Geology

These samples were taken from a relatively wide marble belt which trends roughly northeast through northern South Sherbrooke Township. Within the marble belt are concordant paragneiss units and semiconcordant granitic and pegmatitic bodies. The marble in the belt consists generally of fine- to medium-grained granoblastic calcitic marble.

Local Geology

1891/1892/1893—Detailed mapping in this area (Figure 84) shows that much of the marble in this area is fine grained and grey, with alternating light and dark grey laminations. More coarsely crystalline marble is generally white, with minor amounts of graphite and phlogopite. Small units of dolomitic marble and silicate segregations also occur locally. The silicate segregations occur within the marble as pods or blocks of white plagioclase-rich rock. Thin metasedimentary units cut the marble, striking roughly in an easterly direction. In the middle of the map area is a 300 to 350 m wide granite body that has not apparently altered the adjacent marbles.

1903—Marble in this local map area (Figure 85) is grey laminated with a variable impurity content. Grey and buff laminated marble occurs throughout the area, and is generally low in impurity content. Narrow beds of dolomitic marble occur primarily in the southeast portion of the map area. Granite and pegmatite units intrude conformably into the marble.

Previous Geological Work

South Sherbrooke Township has been mapped by Hewitt (1964a) and in part by Wilson and Dugas (1961).

Chemistry

Most of the samples taken from this marble belt (samples 493, 494, and 1880 to 1904) have low SiO_2 contents, usually less than 2 weight percent. Most of the "calcitic marble" samples in this area are actually of dolomitic calcitic marble composition, with the MgO content ranging from 4 to 9 weight percent. Trace and metallic element contents are low in all samples in this belt.

Potential

The number of metasedimentary and metaigneous units within this grey marble make this an unfavourable area for filler material. It is possible that areas with no contaminants exist, possibly across strike in the belt.

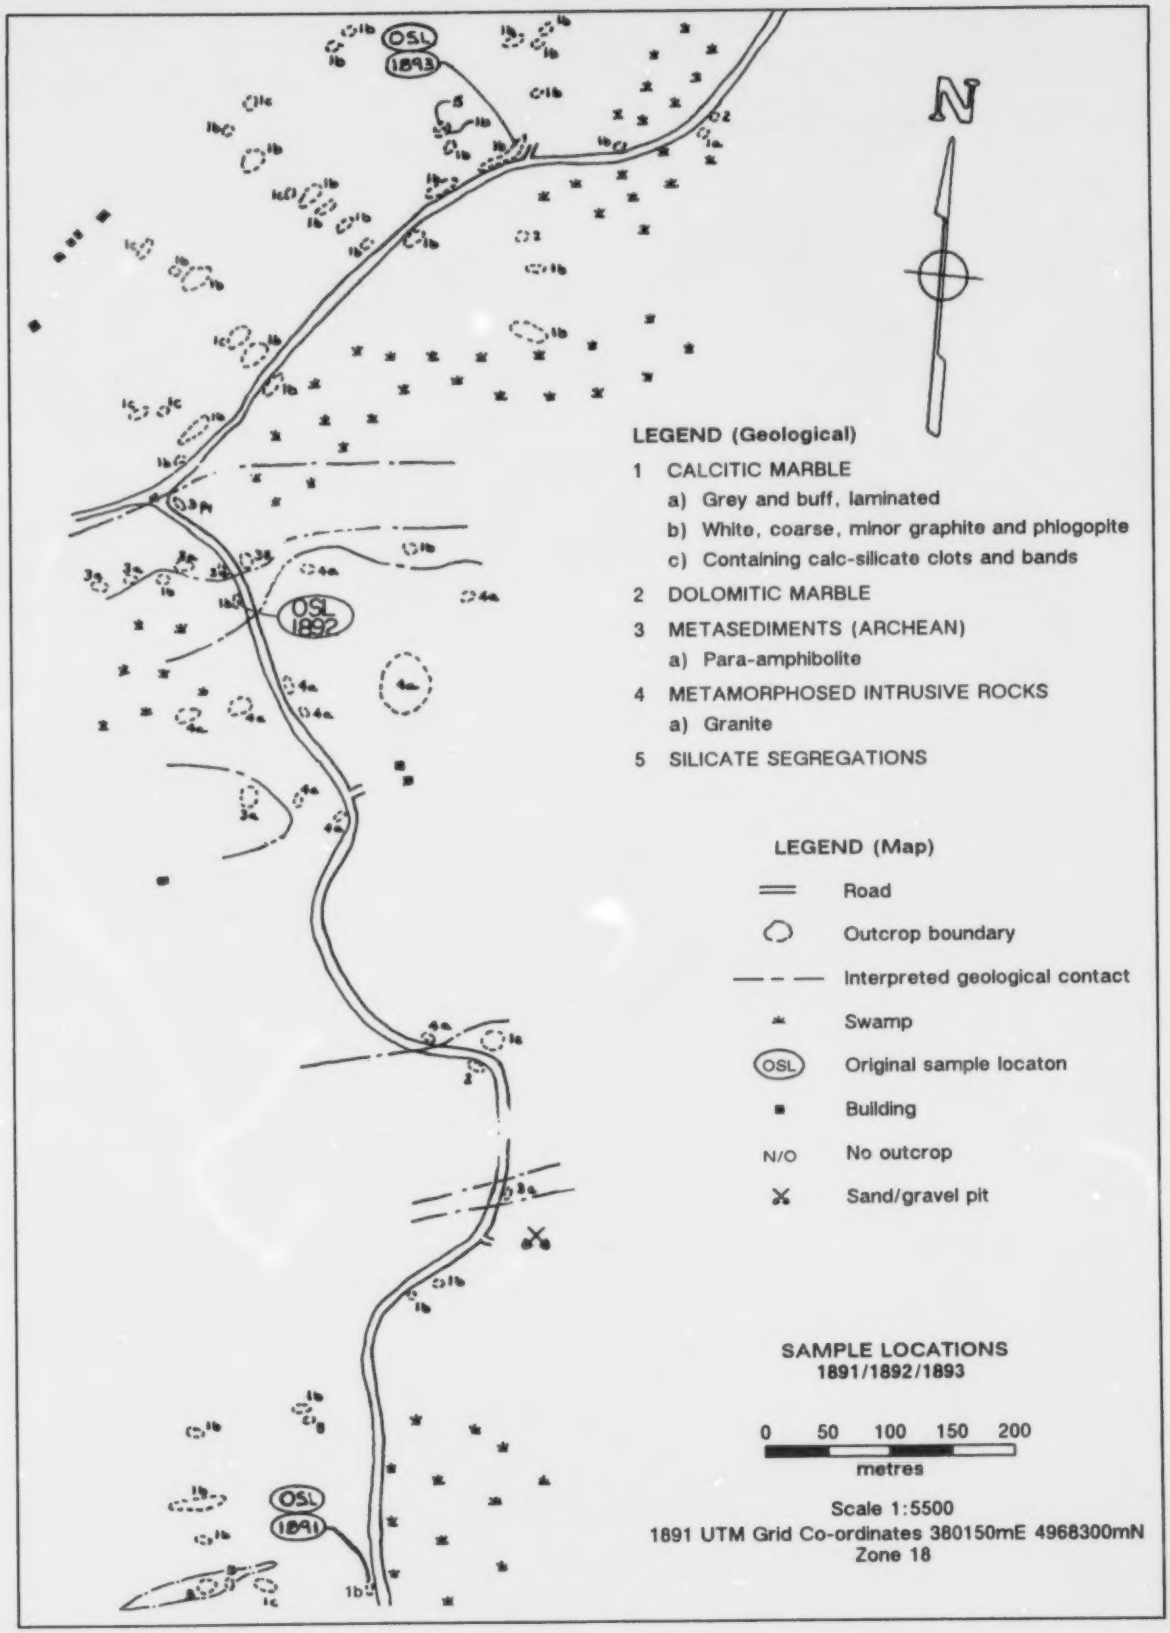

Figure 84. *Location Map, Samples 1891, 1892, and 1893.*

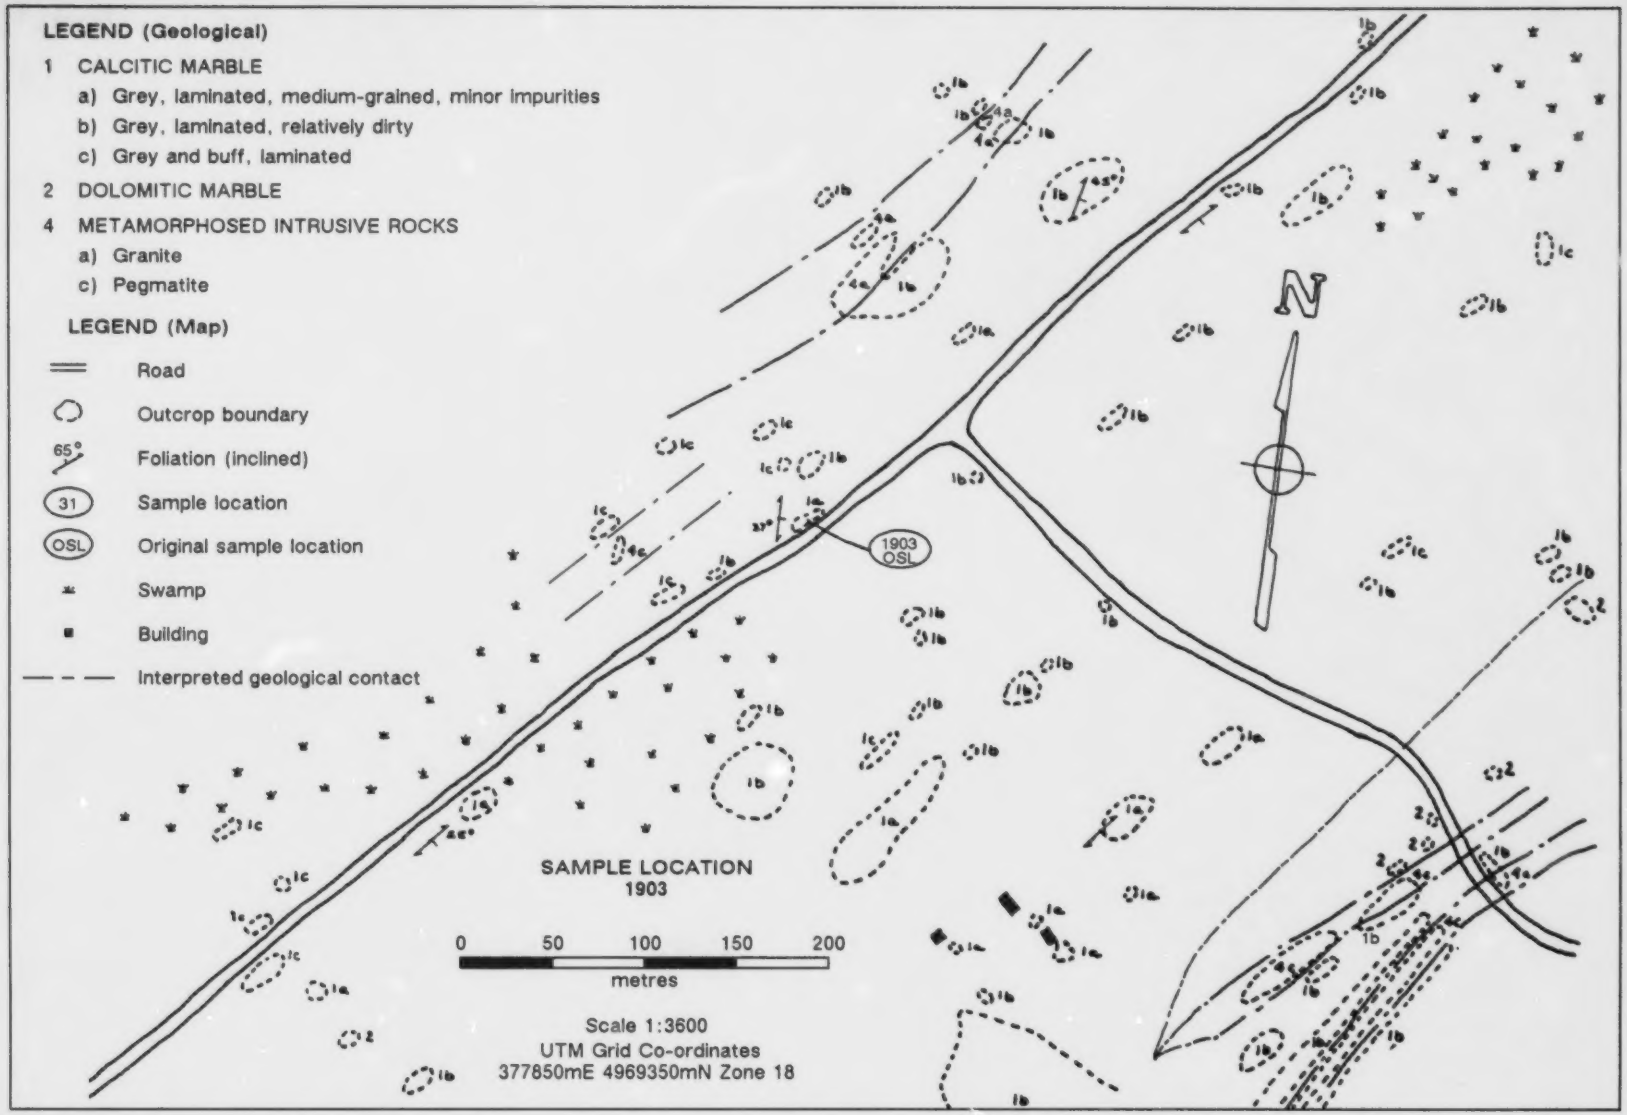

Figure 85. *Location Map, Sample 1903.*

DOLOMITIC MARBLE MAP AREAS

Table 12 is a list of the dolomitic marble map areas mapped during the course of the survey. Dolomitic marble map areas were selected on the basis of the chemical contents of the three predominant elements, CaO, MgO, and SiO_2 in marble. In order to warrant mapping, the marble from these areas had to fit the requirements of containing less than 1.5 weight percent SiO_2, with the CaO/MgO ratio on the order of 1.4.

MAP AREA 3

Location

Southeast corner, Madoc Township.

Map reference: NTS 31C/11; UTM 307050mE, 4931700mN, Zone 18.

Access

1 km south of Highway 7, one concession east of the Madoc turnoff, Concession IX, Lot 1.

Regional Geology

Sample 3 was taken from the southern extension of the main marble belt that runs through Madoc Township. The belt is bounded to the south by a granitic intrusion and to the north by metasediments. Numerous small metasedimentary and intrusive rock units outcrop within the belt.

Local Geology

This area is underlain chiefly by dolomitic marble with some narrow calcitic marble bands (Figure 86). Most of the carbonate rock is white, with lesser amounts of fine-grained grey marble. Impurities within the dolomitic marble can total up to 20 percent, occurring as clots and bands of silicate material. The nature of the contact with the granite is unknown, as a long linear swamp overlies the area adjacent to the granite.

Previous Geological Work

Madoc Township has been mapped by Wilson (1940a) and Hewitt (1964a, 1968).

Chemistry

The majority of samples from this area (samples 2 to 8, 47, and 188 to 198) are dolomitic in composition, containing upwards of 2 weight percent SiO_2. Trace and metallic element contents are low in most samples (for example, sample 3, Appendix A). Sample 188c (Appendix A) is the exception in this region of the marble belt, with almost 0.2 weight percent Cu.

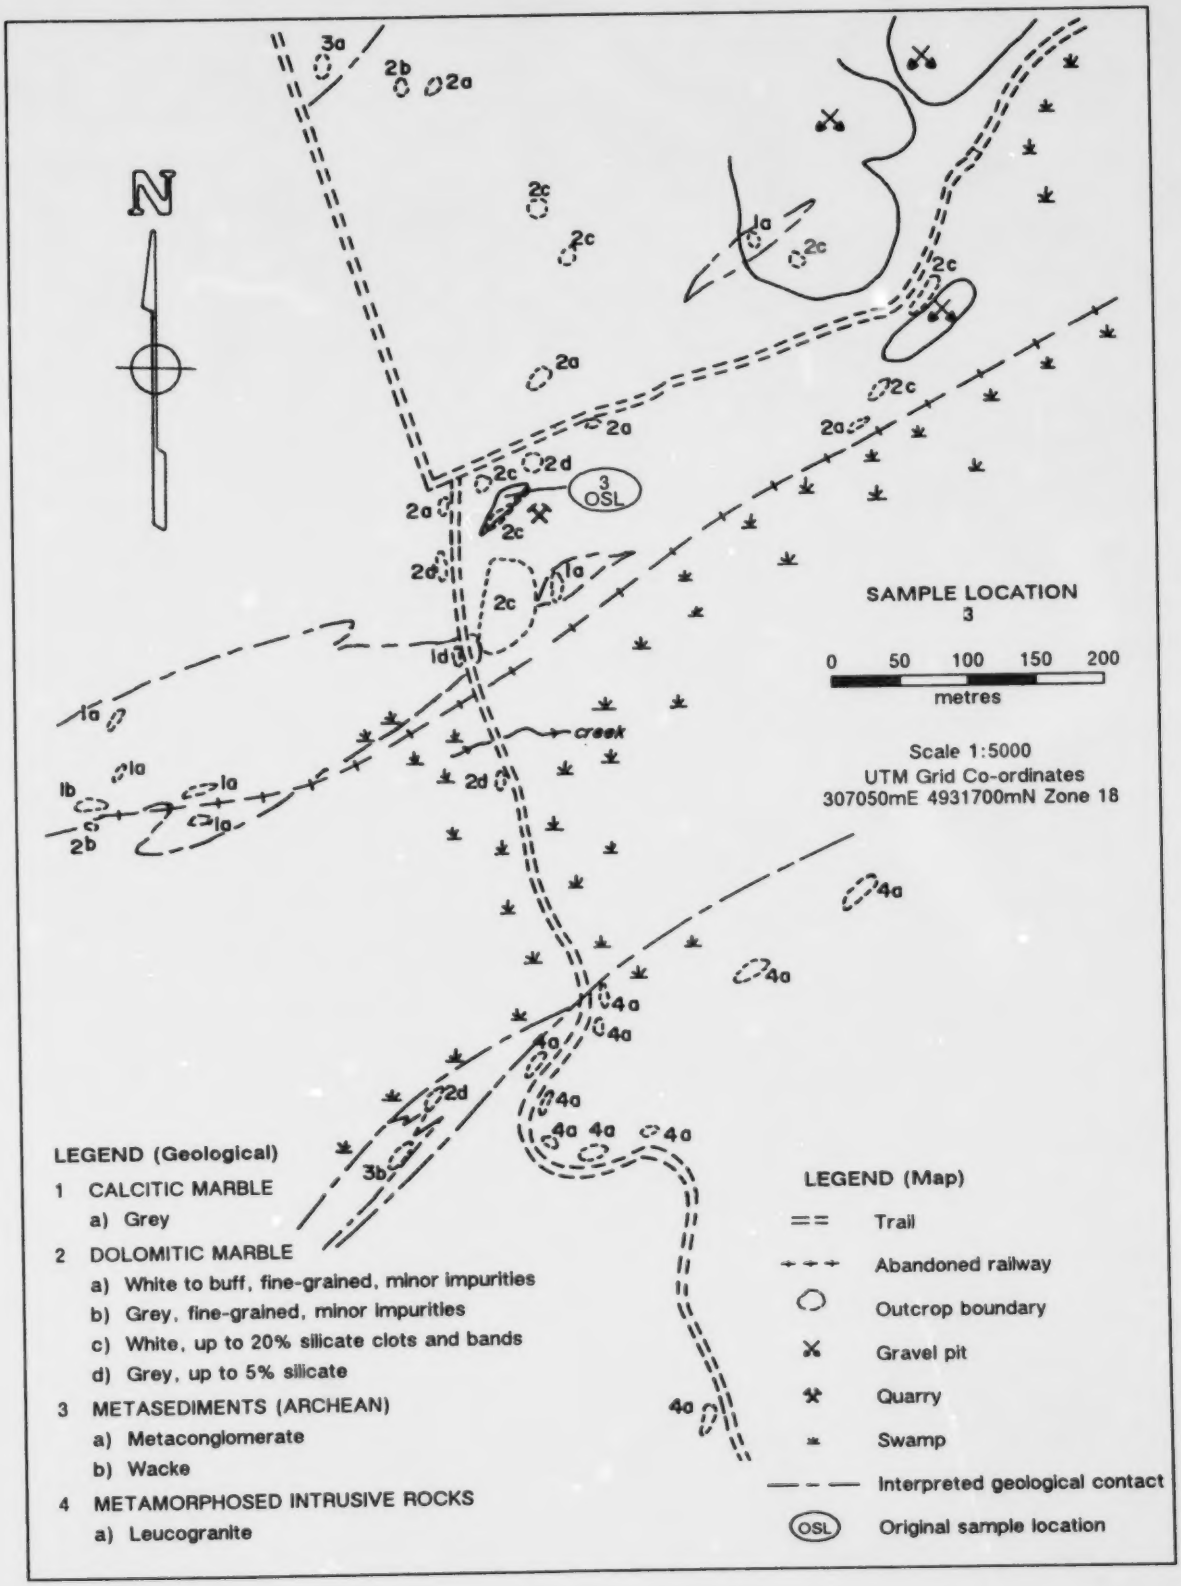

Figure 86. *Location Map, Sample 3.*

MAP AREA 44/45a/45b

Location

West-central Madoc Township.

Map reference: NTS 31C/12.

44—UTM 298500mE, 4940750mN, Zone 18.

45a/45b—UTM 298350mE, 4940800mN, Zone 18.

Access

Turn west at Fox Corners from Highway 62; sample 44 has been taken from one of the two small test pits, Concession V, Lot 19. Samples 45a and 45b were taken from a roadside outcrop approximately 200 m east of the Moira River. The samples were taken from separate marble units occurring within the outcrop.

Regional Geology

These samples were taken from a marble unit which covers most of the central portions of Madoc Township. The marble is intruded to the north and south by granite and is overlain in the vicinity by Paleozoic carbonate rocks. Within the marble are small units of metasediments and metavolcanics.

Local Geology

Detailed mapping in the area (Figure 87) has revealed the presence of marbles of both calcitic and dolomitic composition. Calcitic marble varies from grey fine grained to white crystalline, and grades from only minor impurities to greater than 30 percent impurities. Talc-muscovite occurs in at least one location within the dolomitic marble. The marble grades toward the west to impure marble, where it is interbedded with minor wacke.

Previous Geological Work

Madoc Township has been mapped by Miller and Knight (1914), Wilson (1940a), Hewitt and Satterly (1957), Hewitt (1964a), and Hewitt (1968).

Chemistry

Regional samples from this belt (samples 17 to 45) vary considerably in marble composition. Samples vary from pure calcite marble at sample location 3 (2 km southeast of location 44) to pure dolomite marble at sample location 44; SiO_2 content varies from nearly 0 percent to greater than 20 percent SiO_2. Trace and metallic element contents are at background levels throughout the entire belt.

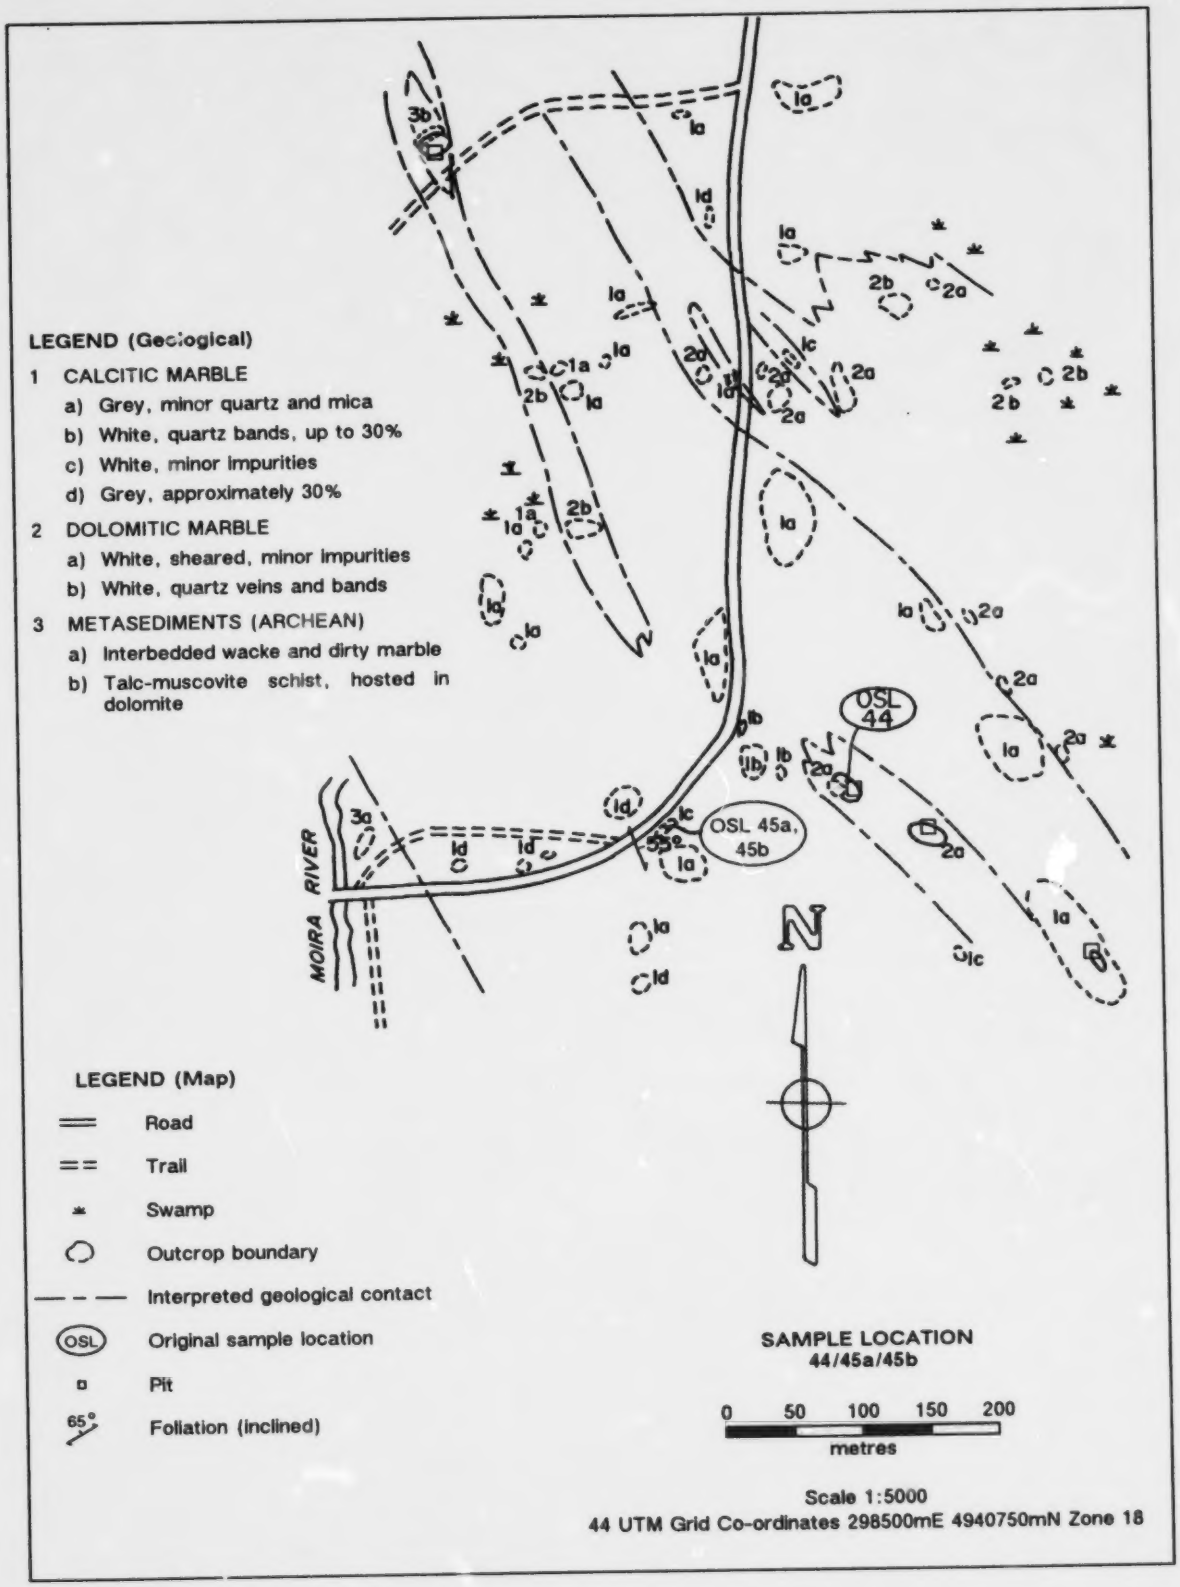

Figure 87. *Location Map, Samples 44, 45a, and 45b.*

MAP AREA 306

Location

East-central Mayo Township.

Map reference: NTS 31F/4; UTM 298500mE, 4940750mN, Zone 18.

Access

Less than 1 km north of Gin Lake and east of the southern tip of Wannamaker Lake. Approximately 6 km south of McArthurs Mills along a gravel road, Concession VII, Lot 22.

Regional Geology

Sample 306 was taken from a marble belt trending northeast across Dungannon and Mayo townships. The belt is from 2 to 3 km in length. The marble belt is bounded by metasediments on all sides, with only minor intrusive rocks in the marble zone. Many metasedimentary units occur concordantly within the marble unit, although these are generally discontinuous along strike. Marble samples taken across the belt are predominantly dolomitic in composition.

Local Geology

This map area is made up of several units of calcitic and dolomitic marble, with intercalated metasediments (Figure 88). Most of the marble is dolomitic, with only minor amounts of interbedded calcitic marble. The marble is for the most part grey, with varying amounts of pyrite, phlogopite, and calc-silicate material in clots. Metasedimentary units include hornblende amphibolite, hornblende-garnet amphibolite, and quartzite. These units are normally between 50 and 75 m wide, with some of the smaller units pinching out along strike.

Previous Geological Work

Mayo Township was mapped by Hewitt and James (1956) and Hewitt (1964a).

Chemistry

Most of the samples from this belt (samples 300 to 313) are dolomitic in composition, with low trace and metallic element contents (for example, sample 306, Appendix A). Silica content is variable throughout the belt, ranging from nearly 0 to greater than 20 weight percent.

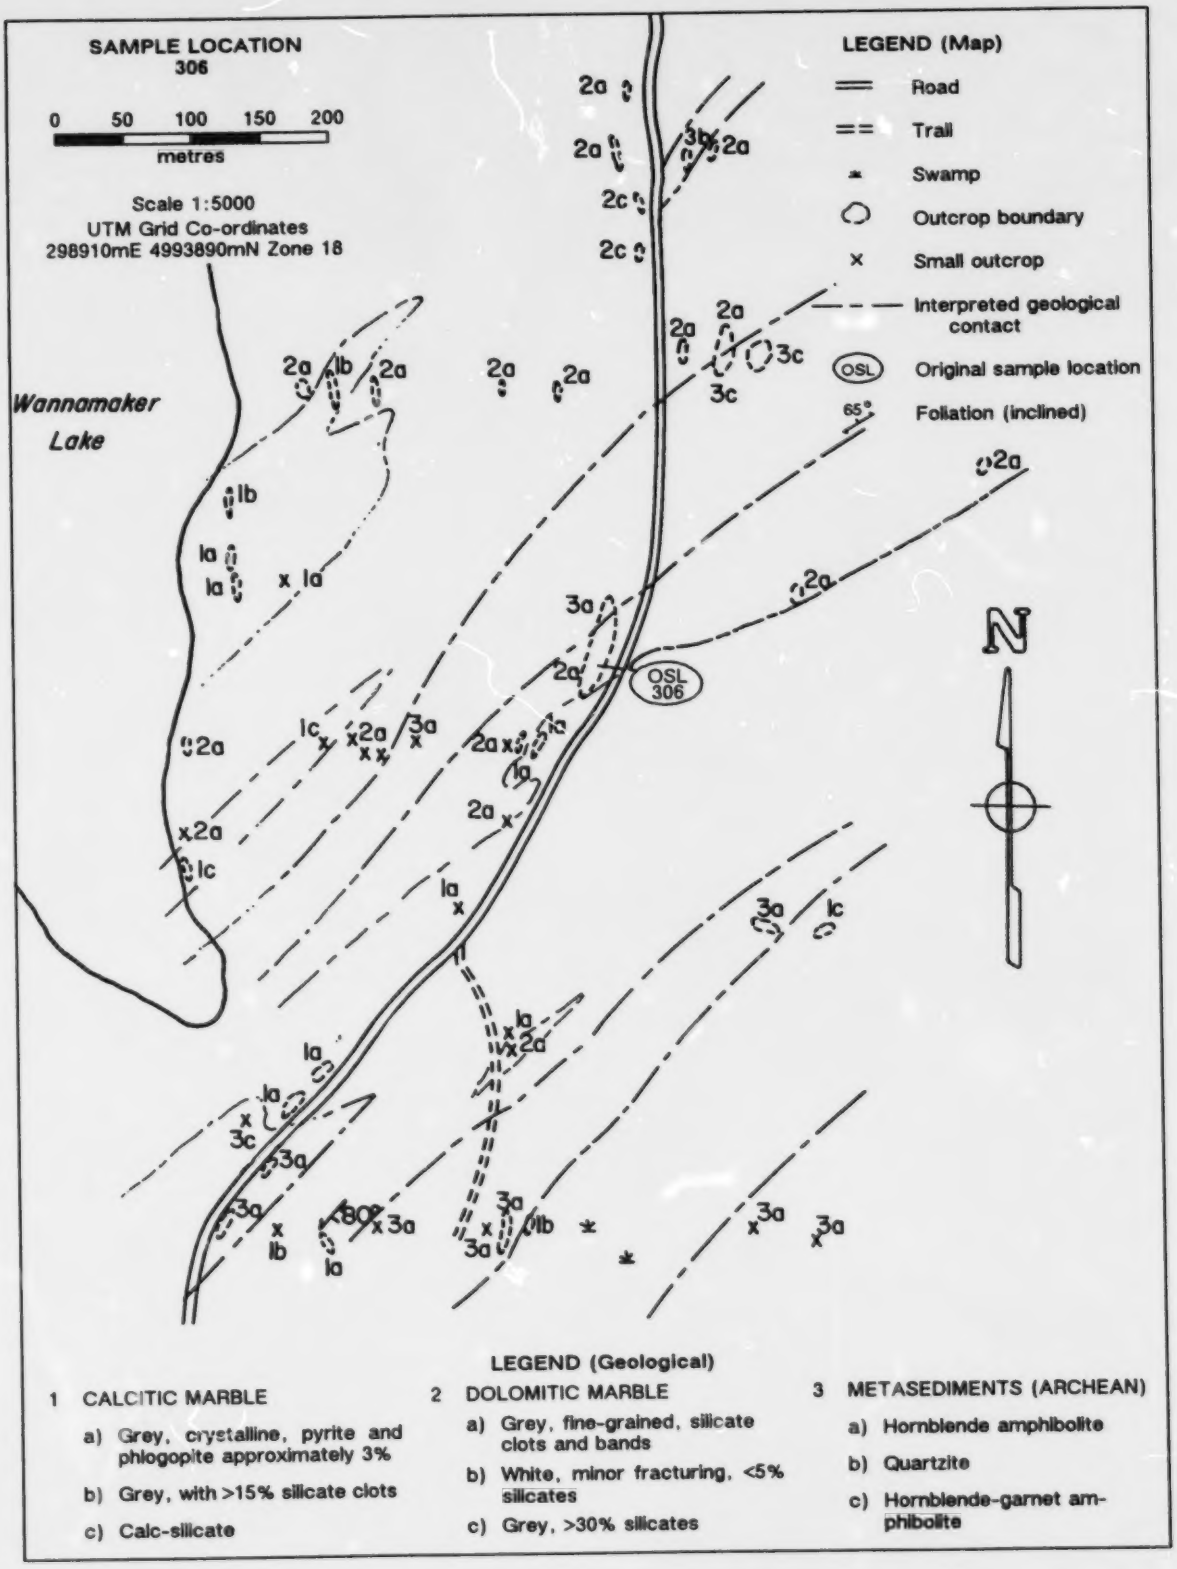

Figure 88. *Location Map, Sample 306.*

MAP AREA 419

Location

Northeast portion of Dungannon Township.

Map reference: NTS 31F/4; UTM 278860mE, 4991200mN, Zone 18.

Access

Sample 419 was taken from the former McMillan Quarry, approximately 1.4 km east on a quarry road, 1.5 km west of York River, Concession X, Lot 28.

Regional Geology

Sample 419 is from an areally extensive marble belt which runs through Faraday, Dungannon, and Mayo townships in an east-northeasterly direction. The marble is interbedded with para-amphibolite and paragneiss, which occur as bands ranging from a few metres up to 0.5 km in width.

Local Geology

Detailed mapping indicates that the marble zone is very narrow, with the true width being represented closely by that of the quarry (Figure 89). The quarry is approximately 20 m wide by 40 m long, and is flanked on both sides by paragneiss and/or biotite schist. The marble band dips 60° northwest with the metasedimentary bands. Marble within the quarry is white and dolomitic in composition, with some minor ptygmatic silicate folds. Quarried blocks are up to a metre square without fracturing. Marble at the east of the map area is calcitic, coarse grained, and orange in colour. Minor amounts of tremolite and graphite occur within this orange marble.

Previous Geological Work

Dungannon Township has been mapped by Hewitt and James (1956). McMillan Quarry has been mapped by Hewitt (1964c).

Chemistry

Regional samples taken in this portion of the marble belt (samples 408 to 420) have varying silica contents ranging from less than 1 percent to over 20 percent by weight. Marble samples also range in composition from calcitic to dolomitic. Sample 412 (Appendix A) has a high Cu content (2040 ppm), although this sample also has a high SiO_2 content. Sample 415 (Appendix A) has a high Sr content (2290 ppm). All other samples have low trace and metallic element contents (for example, sample 419, Appendix A).

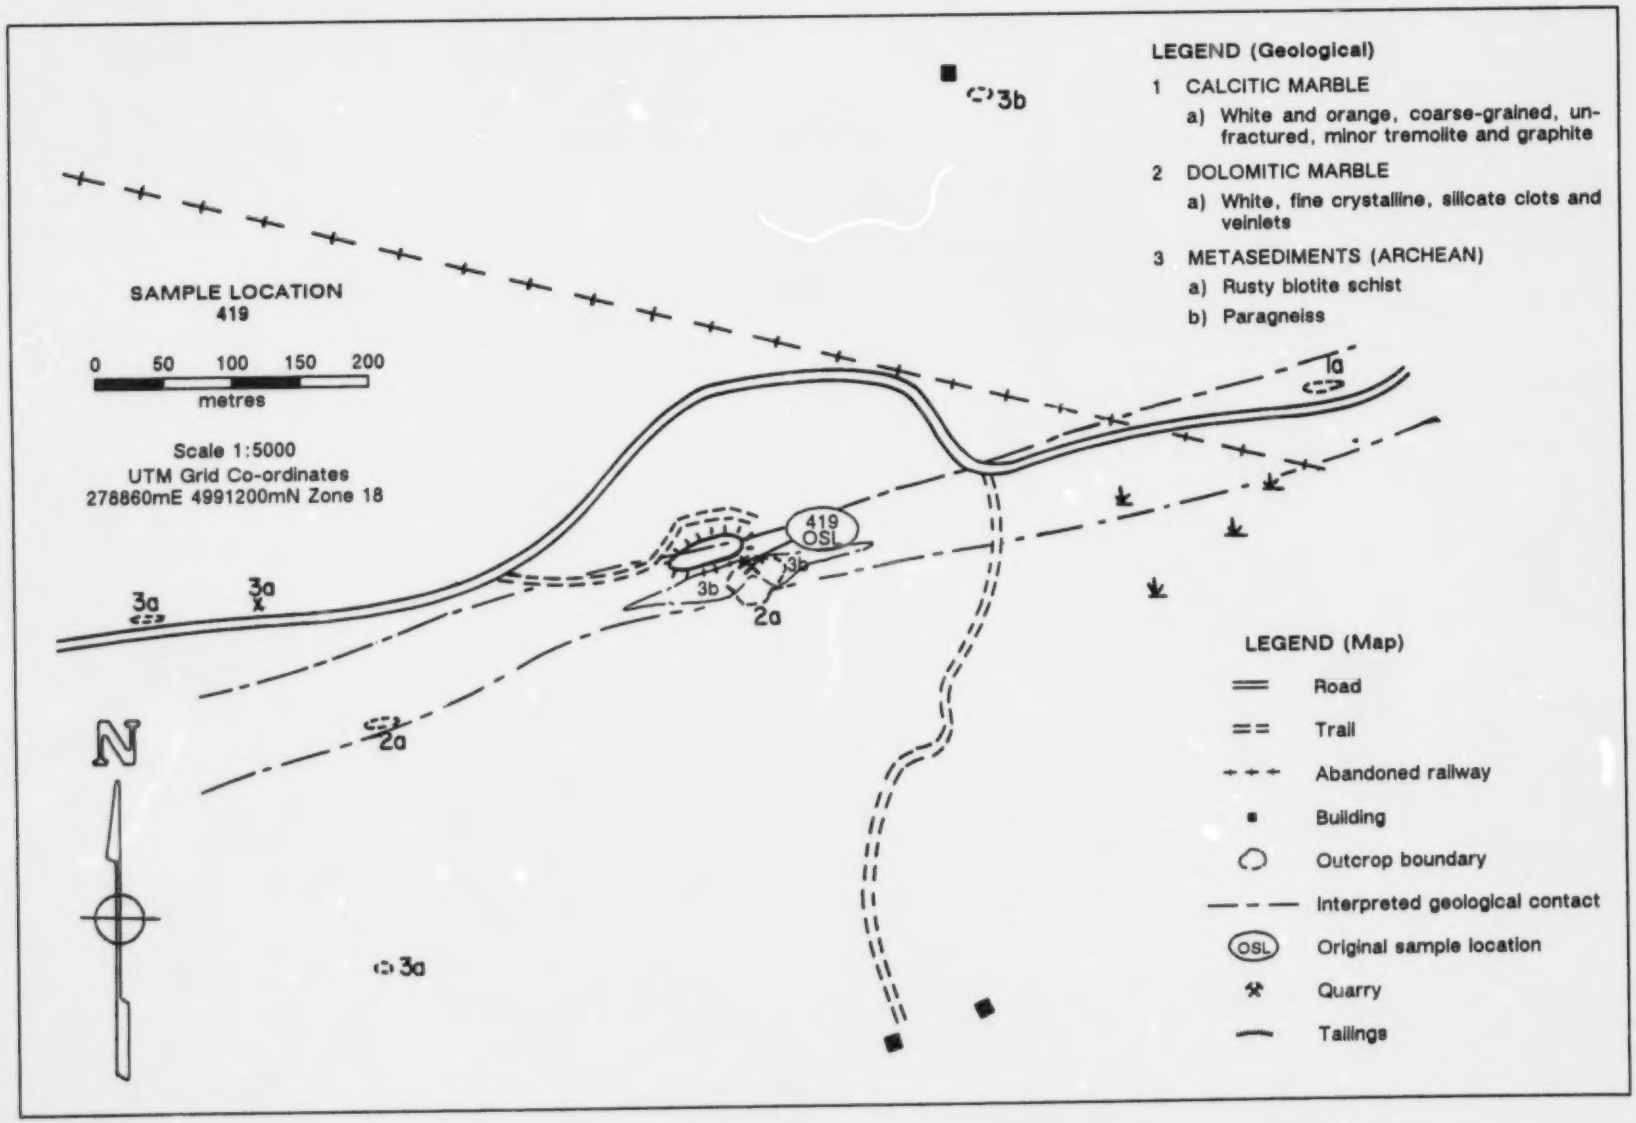

Figure 89. *Location Map, Sample 419.*

MAP AREA 439

Location

South-central Kennebec Township.

Map reference: NTS 31C/10; UTM 345200mE, 4948150mN, Zone 18.

Access

South of Highway 7, on a road running on the south side of Salmon River, east end of Horseshoe Lake, Concession IV, Lot 6.

Regional Geology

Sample 439 is from a narrow northeast-trending marble belt bounded to the north and south by metasediments. This narrow belt is slightly south of a much wider belt just south of Highway 7. Both belts contain pegmatite dikes and numerous metasedimentary bands, all concordant with the marble structure.

Local Geology

Detailed mapping indicates that the marble occurs as a narrow unit with inclusions of amphibolite and pegmatite (Figure 90). Most of the marble is coarse grained and dolomitic in composition, with various amounts of silicate, amphibolite, and biotite. Metasediments flanking the marble belt are generally schistose, and contain biotite, hornblende, and quartz.

Previous Geological Work

Kennebec Township has been mapped by Meen and Harding (1942) and Hewitt (1964a).

Chemistry

The narrow marble band from which sample 439 was taken (samples 434 to 439) is predominantly dolomitic in composition, with up to 5 percent silica. Trace and metallic element contents are low throughout this unit. A wide belt north of this narrow band, which is not shown on the map, is also predominantly dolomitic although there are several calcitic marble samples from the belt. Silica content ranges up to 20 weight percent for several of the calcitic marble samples. These samples normally have higher trace and metallic element contents, typical of impure marbles.

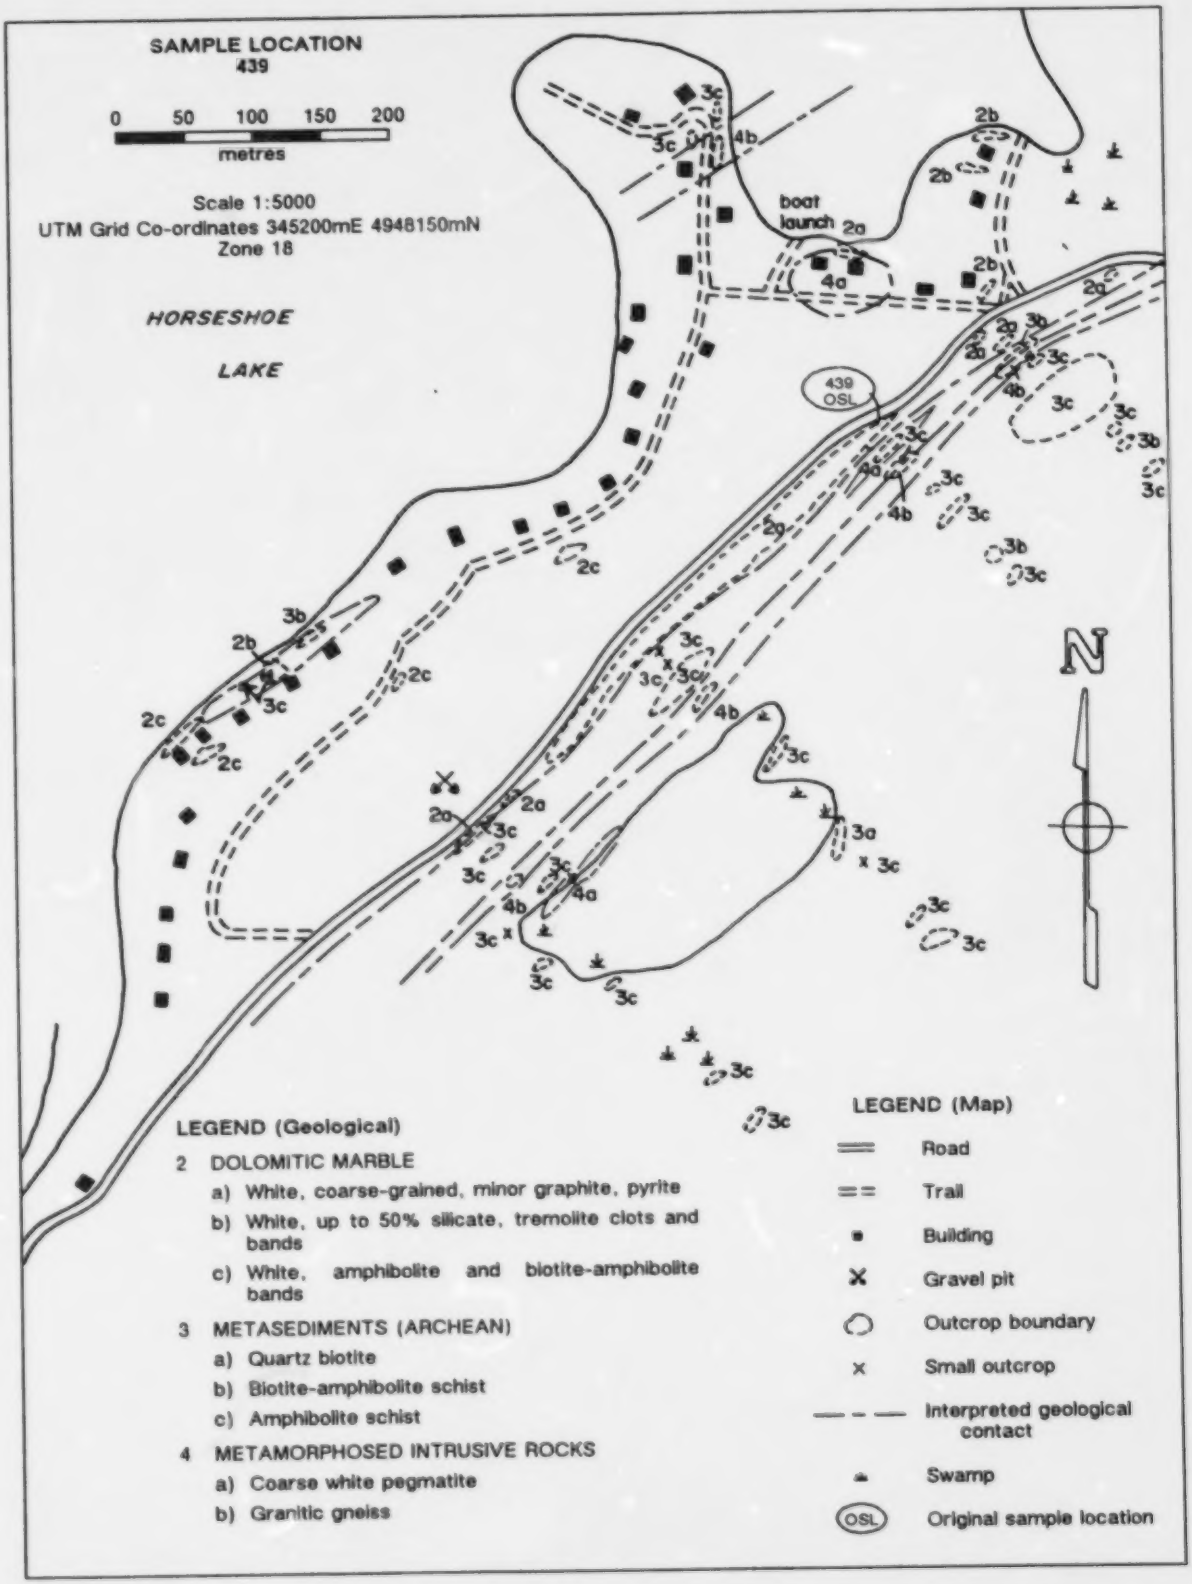

Figure 90. *Location Map, Sample 439.*

MAP AREA 455

Location

West-central Olden Township (at the Kennebec Township boundary).

Map reference: NTS 31C/10; UTM 350550mE, 4956000mN, Zone 18.

Access

South of Highway 7, west of Mountain Grove, 1 km east of Big Clear Lake, Concession I, Lot 17.

Regional Geology

This sample is from a northeast-trending marble belt which runs through Kennebec and Olden Townships. The belt is flanked to the north and south by metasediments, with granitic intrusive rocks adjacent to and within the marble belt. Small metasedimentary units occur within the marble running parallel to the marble belt.

Local Geology

Detailed mapping of this area (Figure 91) shows that the area is underlain mainly by white dolomitic marble. Most of the marble has greater than 5 percent silicate minerals occurring as clots and bands. Metaigneous pegmatite and granite occur within the marble as relatively small units. These intrusive rocks apparently have been altered by reactions with the carbonate material to form a white coarsely crystalling rock type.

Previous Geological Work

Olden Township has been mapped by Harding (1951) and Hewitt (1964a).

Chemistry

Samples in the marble belt (samples 358 to 367 and 442 to 462) have silica contents ranging from less than 1 weight percent to over 20 weight percent. Samples also range from calcitic to dolomitic in composition. Trace and metallic element contents are low throughout the belt with the exception of Sr, which is anomalous in several of the calcitic marble samples. Visual examination along different areas of this belt reveals that silicate banding is prevalent in most of the dolomitic marble.

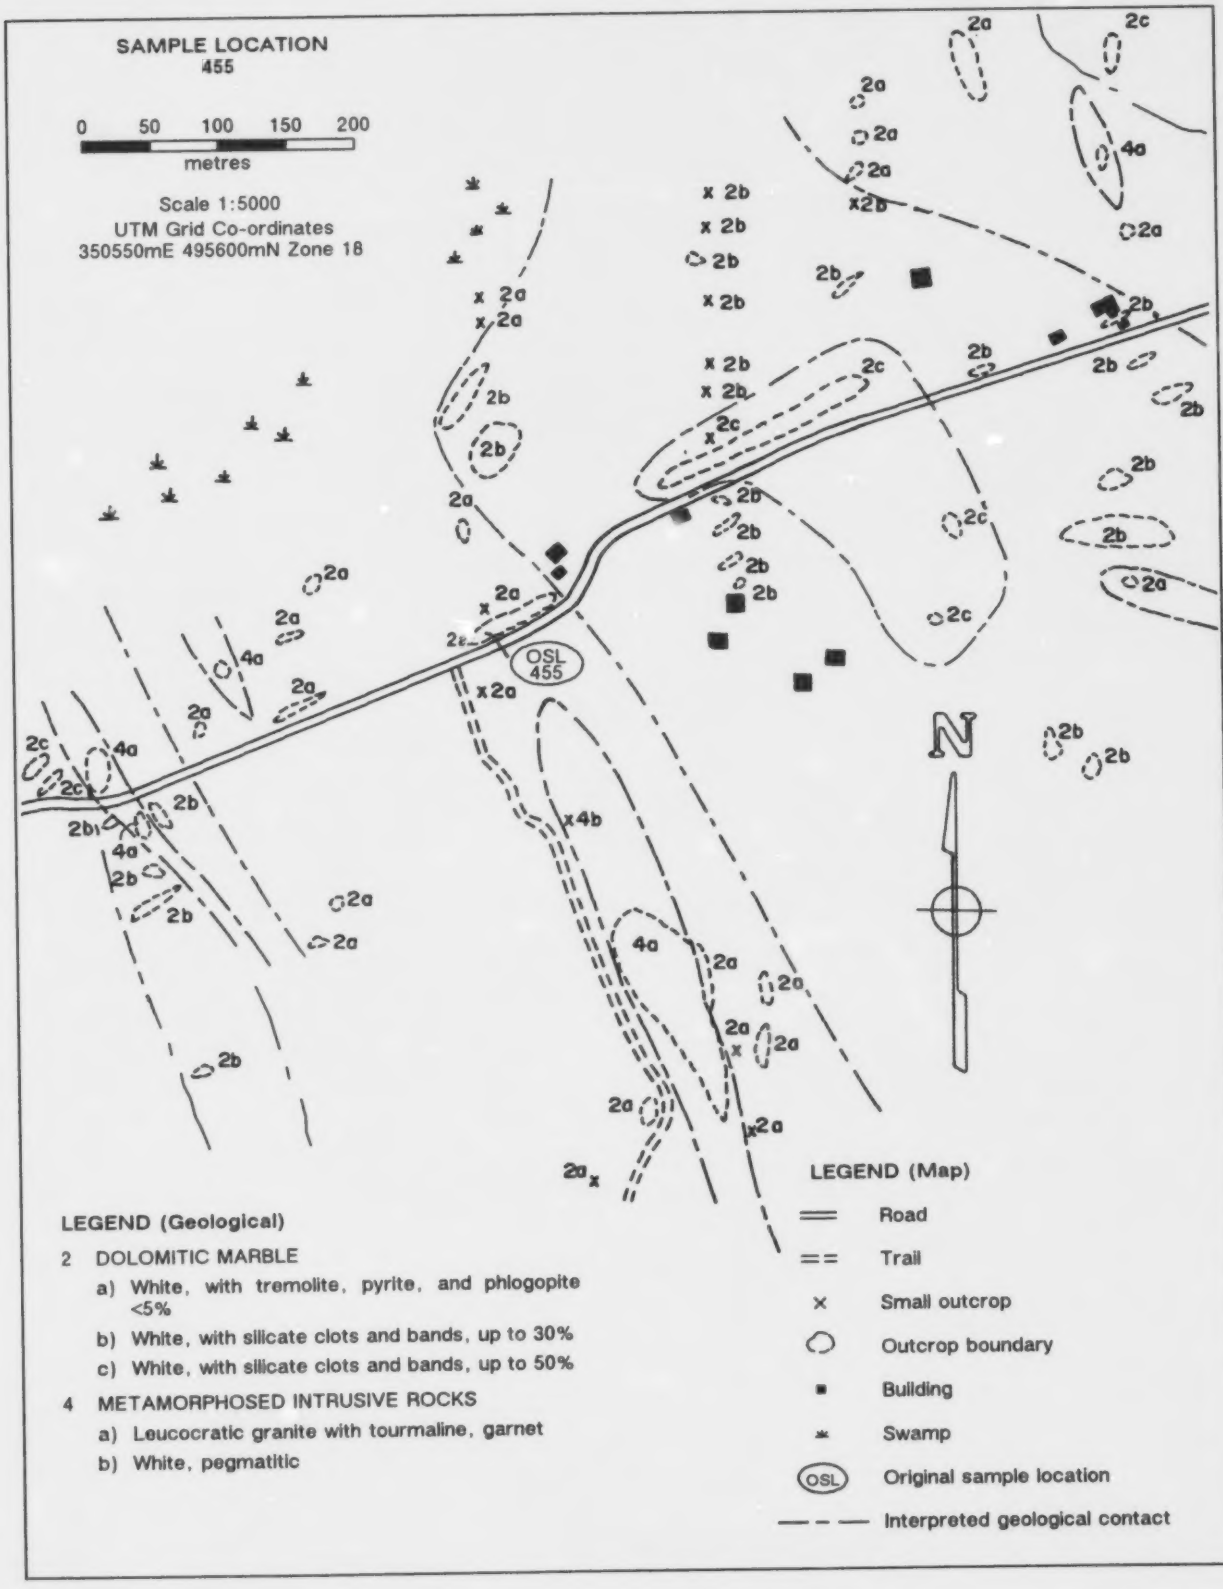

Figure 91. *Location Map, Sample 455.*

MAP AREA 460

Location

West-central Olden Township.

Map reference: NTS 31C/15; UTM 351800mE, 4957100mN, Zone 18.

Access

On the south side of Highway 7, 1.5 km west of the Mountain Grove turnoff, Concession II, Lot 18.

Regional Geology

This sample is from an east-trending marble belt located north of White Lake. The unit is approximately 1 km wide by several kilometres in length. It is bounded by granite gneiss toward the north and metasediments to the south. Metasedimentary and metaigneous units are intercalated within the marble unit; however, these units are discontinuous along strike. Regional samples taken from this belt are predominantly dolomitic in composition.

Local Geology

The detailed map area (Figure 92) is underlain predominantly by white dolomitic marble with varying amounts of amphibole, biotite, and silicate clots. Good clean white marble occurs adjacent to leucogranite outcrops suggesting that there is a connection between the presence of the intrusive rocks and the marble purity. Intrusive rocks are generally concordant to marble foliation in the area, and are discontinuous along strike. Tremolite is associated with locally occurring silica-rich bands.

Previous Geological Work

Olden Township has been mapped by Harding (1951) and Hewitt (1964a).

Chemistry

Samples taken throughout the marble belt are predominantly dolomitic in composition although several calcitic marble samples are present. Silica contents are generally high, while trace and metallic element contents are low.

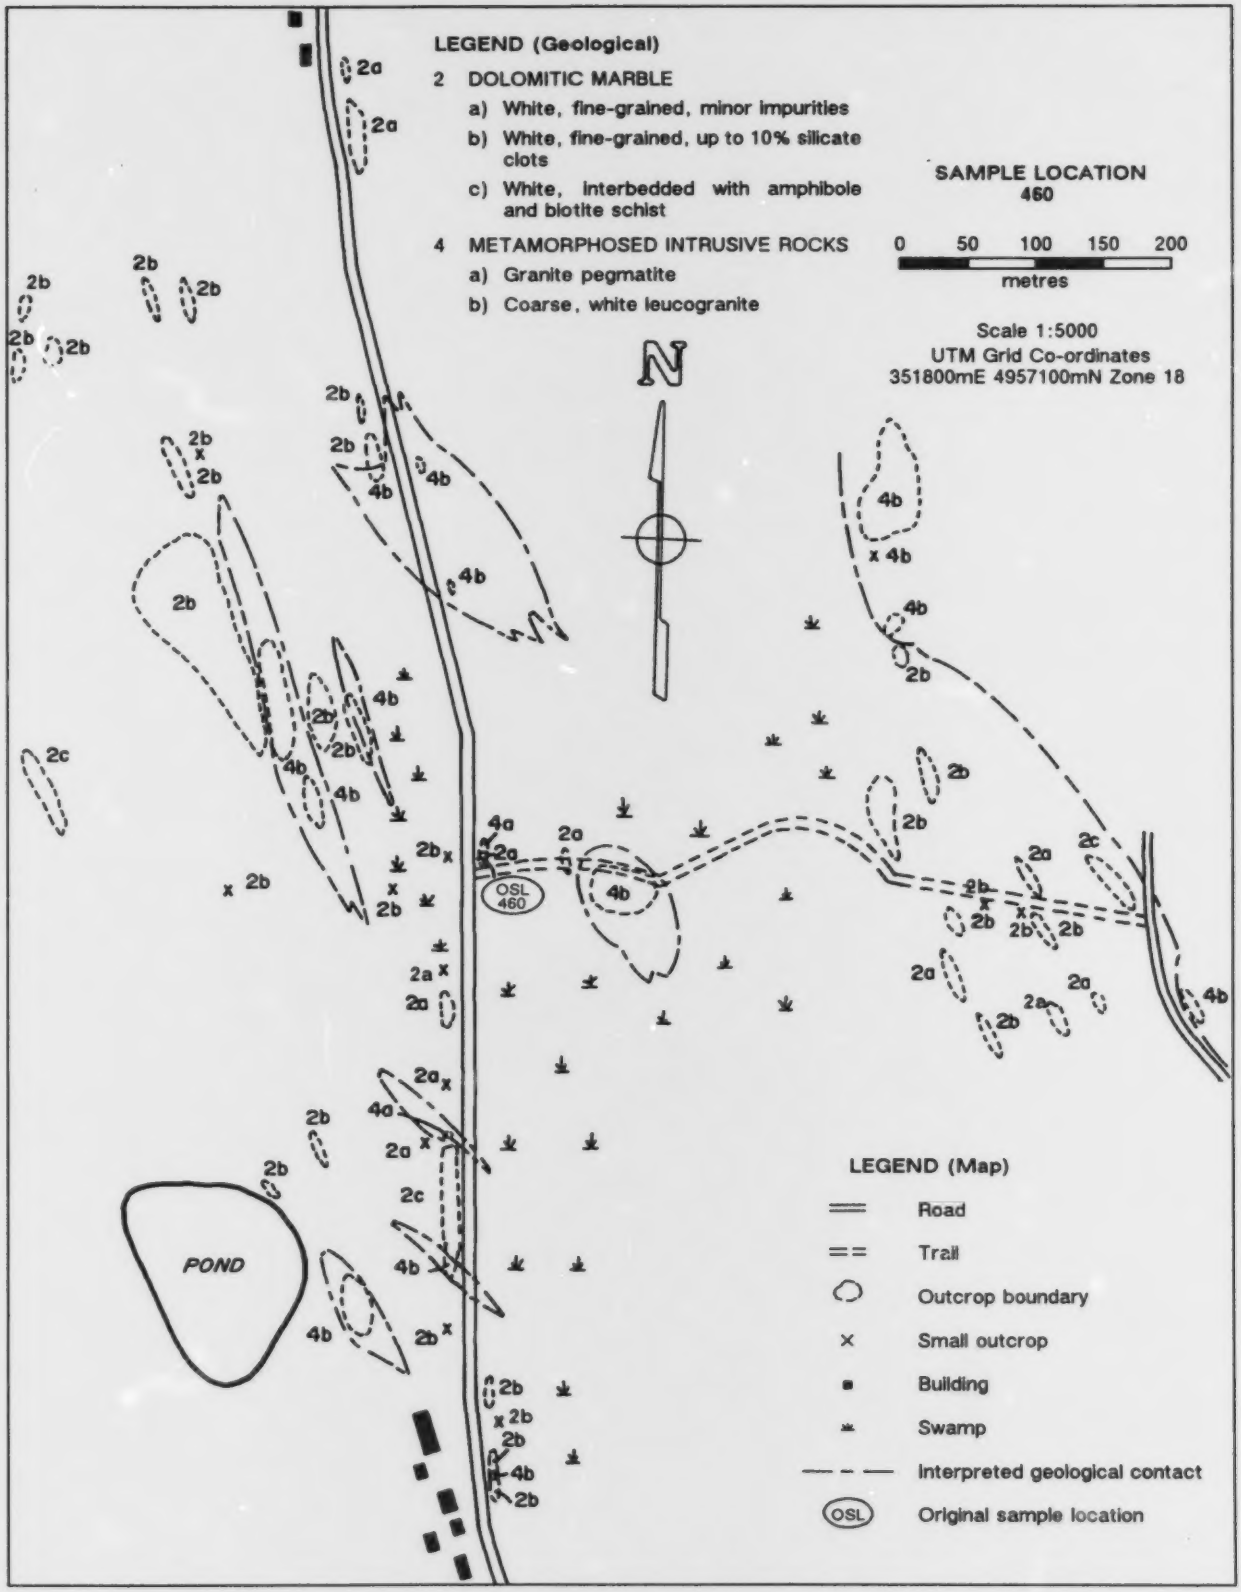

Figure 92. *Location Map, Sample 460.*

MAP AREA 604

Location

Northeast corner of Clarendon Township.

Map reference: NTS 31C/15; UTM 348200mE, 4981350mN, Zone 18.

Access

On the paved road running from Plevna to Ompah, approximately 200 m west of the power line, Concession IV, Lot 38.

Regional Geology

Sample 604 is from the marble unit located centrally within the Ferleigh Syncline. This band is a northeast-trending unit bounded to the north by amphibolite and to the south by amphibolite and paragneiss.

Local Geology

Detailed mapping of this area (Figure 93) reveals that the majority of marble samples are dolomitic with a fine grain size. Silicate clots are prevalent throughout the area, ranging from only a few percent to over 50 percent. Minor amounts of tremolite and biotite occur throughout most of the marble. Amphibolite occurs only in one location and is only exposed over a couple of metres.

Previous Geological Work

Clarendon Township has been mapped by Peach and Smith (1956), Hewitt (1964a), and Pauk (1982, 1987).

Chemistry

Regional sampling in this belt (samples 358 to 367 and 442 to 462) shows that a gradation occurs from dolomitic marble at the southwest end of the belt to calcitic marble toward the northeast. Impurities range from less than 1 percent in a single dolomitic marble sample to over 20 percent for several calcitic marble samples. Trace and metallic element contents are low for all of the samples in this belt.

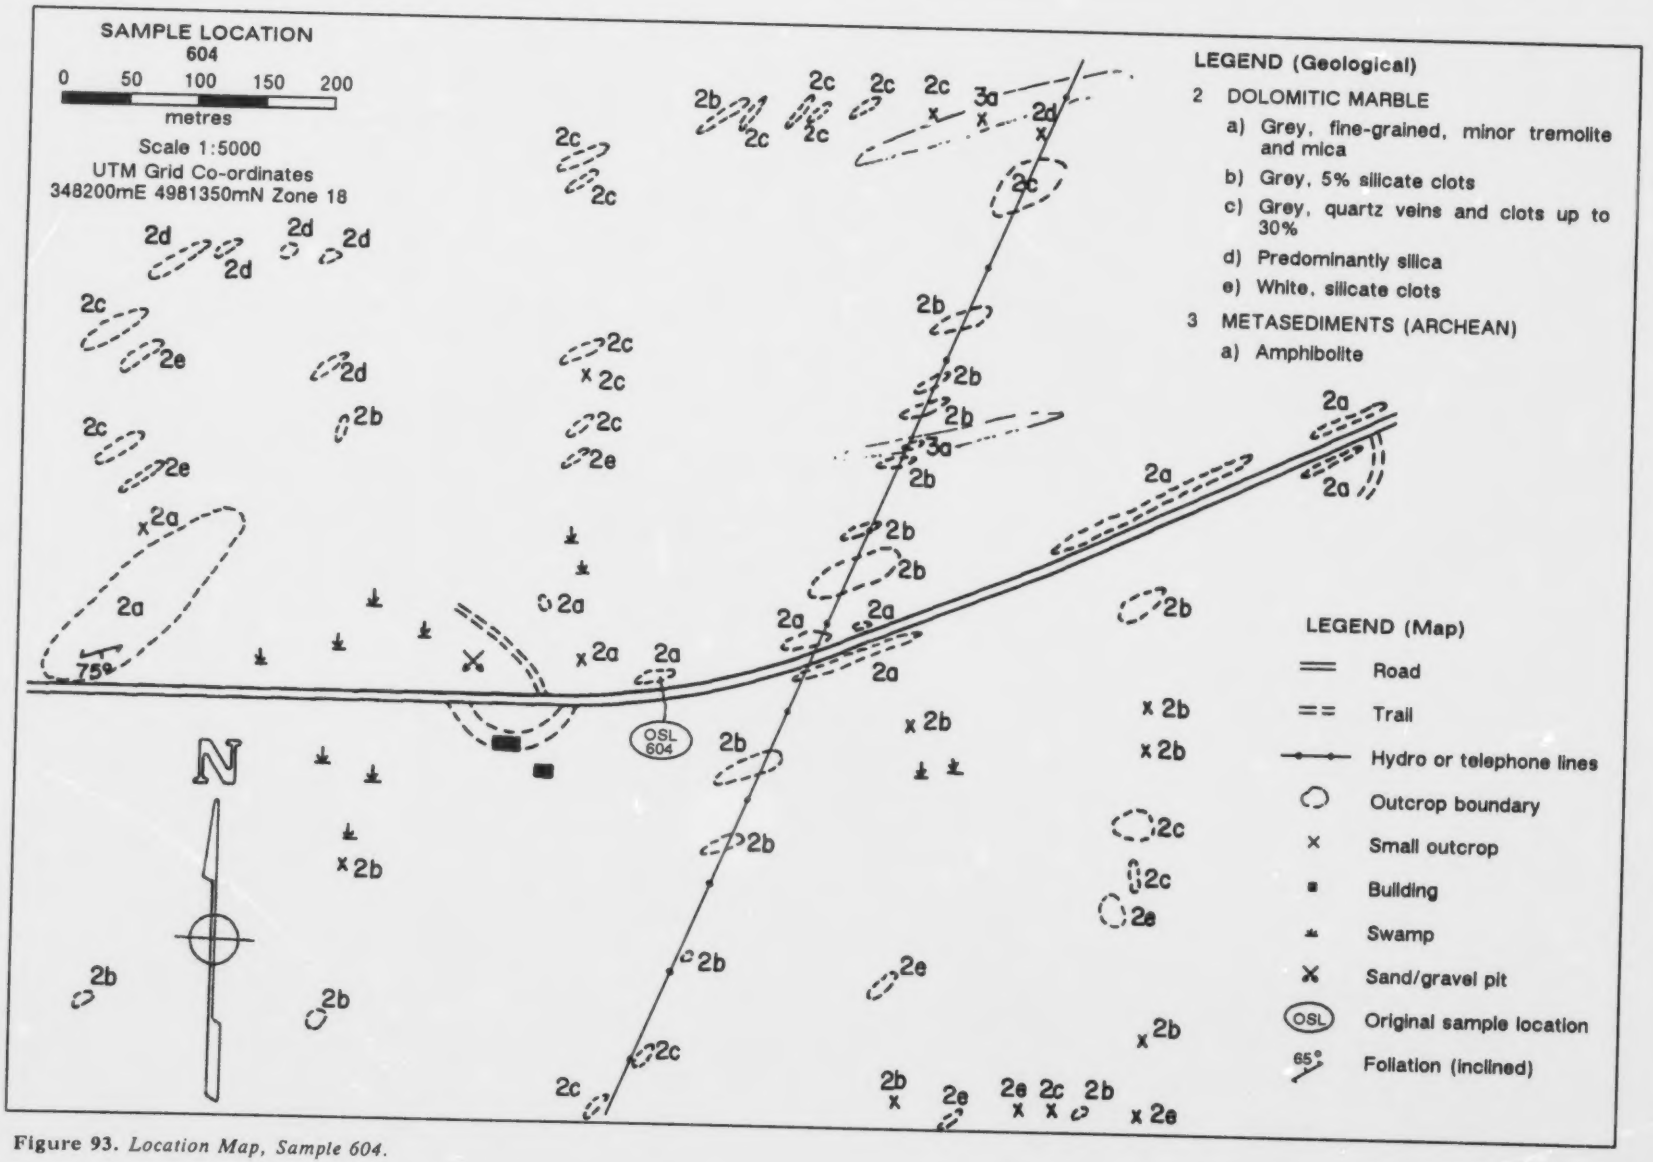

Figure 93. *Location Map, Sample 604.*

MAP AREA 683

Location

East-central Palmerston Township.

Map reference: NTS 31C/15; UTM 368300mE, 4979000mN, Zone 18.

Access

A gravel road approximately 1 km northeast of Snow Road Station, 0.5 km west of North Sherbrooke Township boundary, Concession XI, Lot 12.

Regional Geology

Sample 683 is from a long narrow belt extending northeast from Mississippi Station to Gordon Rapids. The belt rarely exceeds 1 km in width. It is bounded by mafic intrusive rocks to the east and granitic rocks toward the west. Within the belt are several narrow discontinuous amphibolite units. Almost all of the regional samples in this belt were taken from dolomitic marble.

Local Geology

The detailed map area (Figure 94) is underlain by dolomitic rocks of varying purity. Granitic intrusive rocks are in contact with the marble, trending generally north. Neither the marble nor the granite have been altered at their contact. Minor amounts of amphibolite lie in sharp contact with the marble. The majority of marble outcrops are characterized by the presence of silicate material in clots and bands, with lesser amounts of tremolite, chlorite, and pyrite.

Previous Geological Work

Palmerston Township or portions of Palmerston Township have been mapped by Smith (1958), Hewitt (1964a), and Pauk (1982, 1987).

Chemistry

Samples from this marble belt (samples 682 to 686 and 1846 to 1849) are dolomitic in composition, and generally have low SiO_2 contents. Trace and metallic element contents are low in all of the samples in the belt.

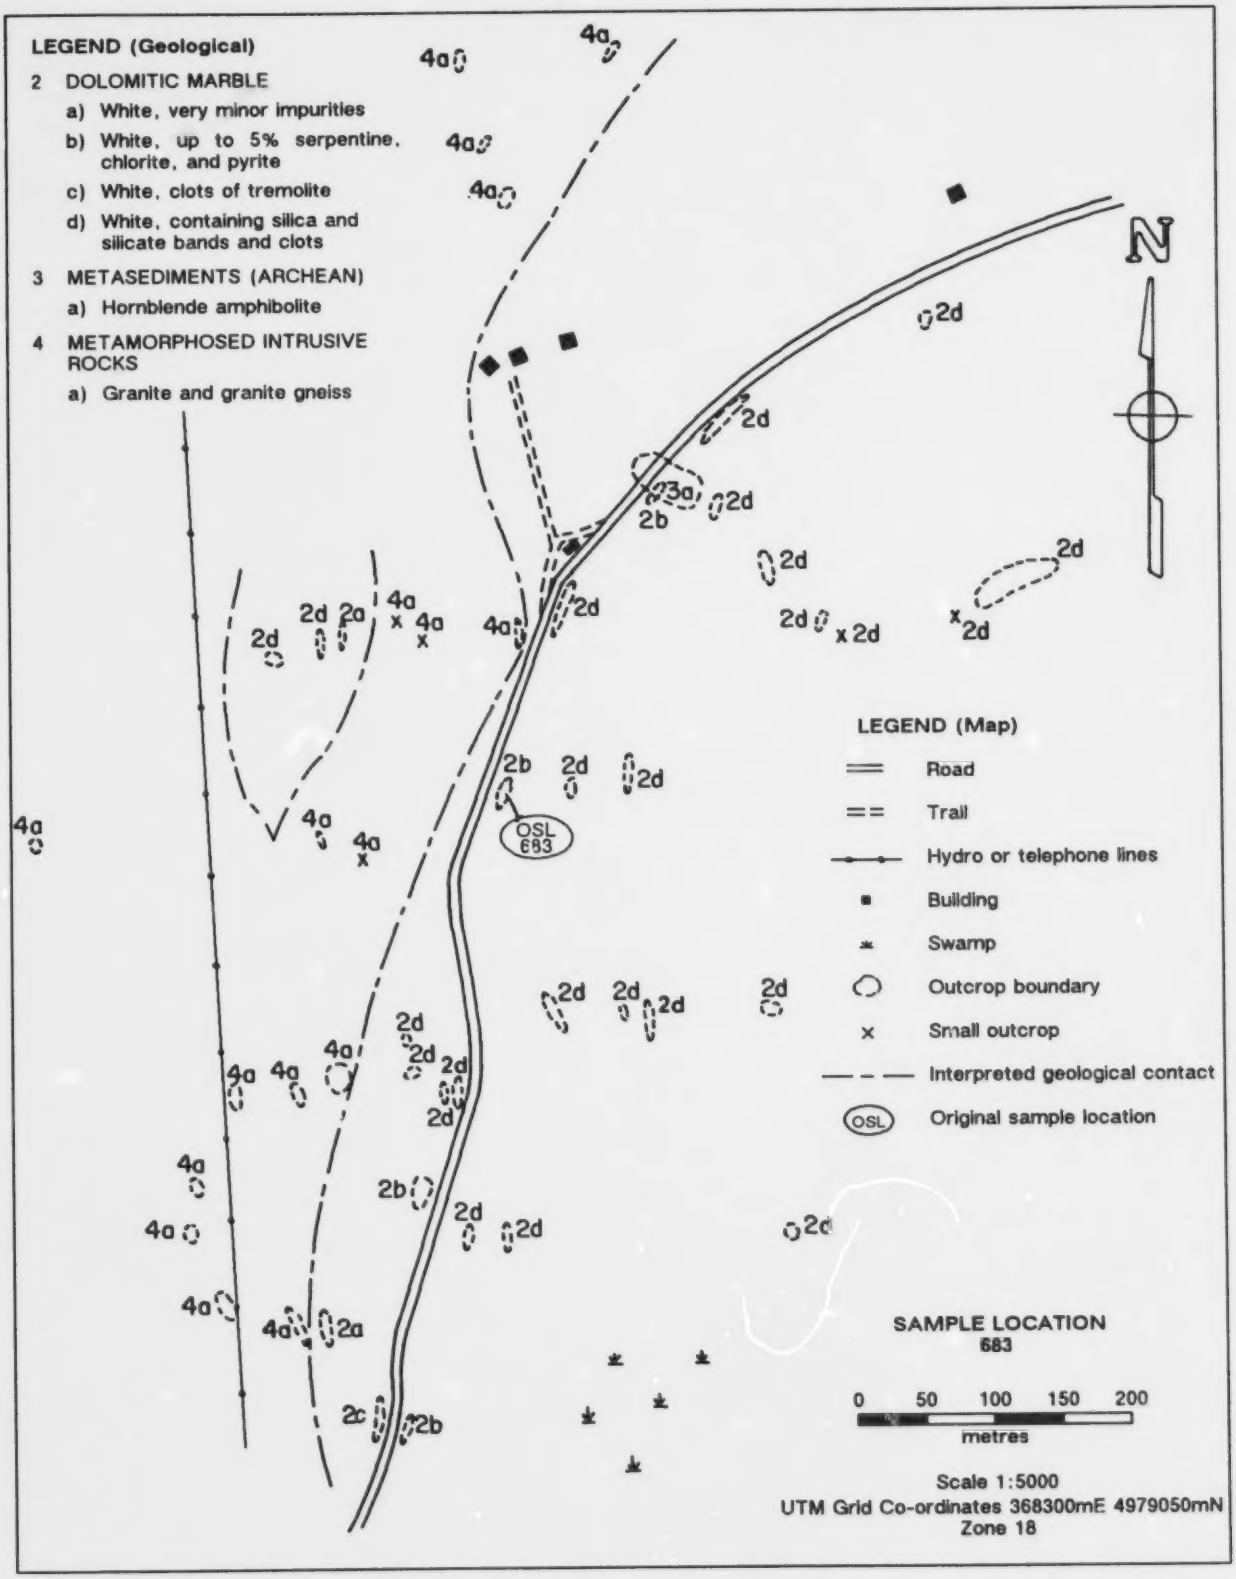

Figure 94. *Location Map, Sample 683.*

MAP AREA 684

Location

Northwestern edge of North Sherbrooke Township.

Map reference: NTS 31C/15; UTM 368950mE, 4979750mN, Zone 18.

Access

On a gravel road approximately 500 m east of Palmerston–North Sherbrooke Township Line, east of Snow Road Station.

Regional Geology

Sample 684 comes from a narrow northeast-trending marble belt. The belt ranges between 0.5 and 1 km in width, and is approximately 20 km in length. The belt is bounded to the northwest by granitic intrusive rocks and to the southeast by mafic intrusive rocks. Within the marble are several, predominantly hornblende amphibolite, bands.

Local Geology

Detailed mapping around the original sample location (Figure 95) indicates that the marble belt is only 150 m wide. All marble outcrops are dolomitic in composition, with silicate clots making up between 5 and 25 percent of the total rock. There is very little alteration of the granite at its contact with the marble.

Previous Geological Work

North Sherbrooke Township has been mapped by Smith (1958) and Hewitt (1964a).

Chemistry

Regional sampling of this narrow belt (samples 682 to 686 and 1846 to 1849) shows that a gradation occurs from dolomitic marble at the southwest end of the belt to calcitic marble at the northeast end. Dolomitic marble sampled a distance away from silicate clots contain up to 3 weight percent SiO_2. Calcitic marble in this belt contains a much higher SiO_2 content, with a varying MgO content. Trace and metallic element contents are low in all samples in this belt.

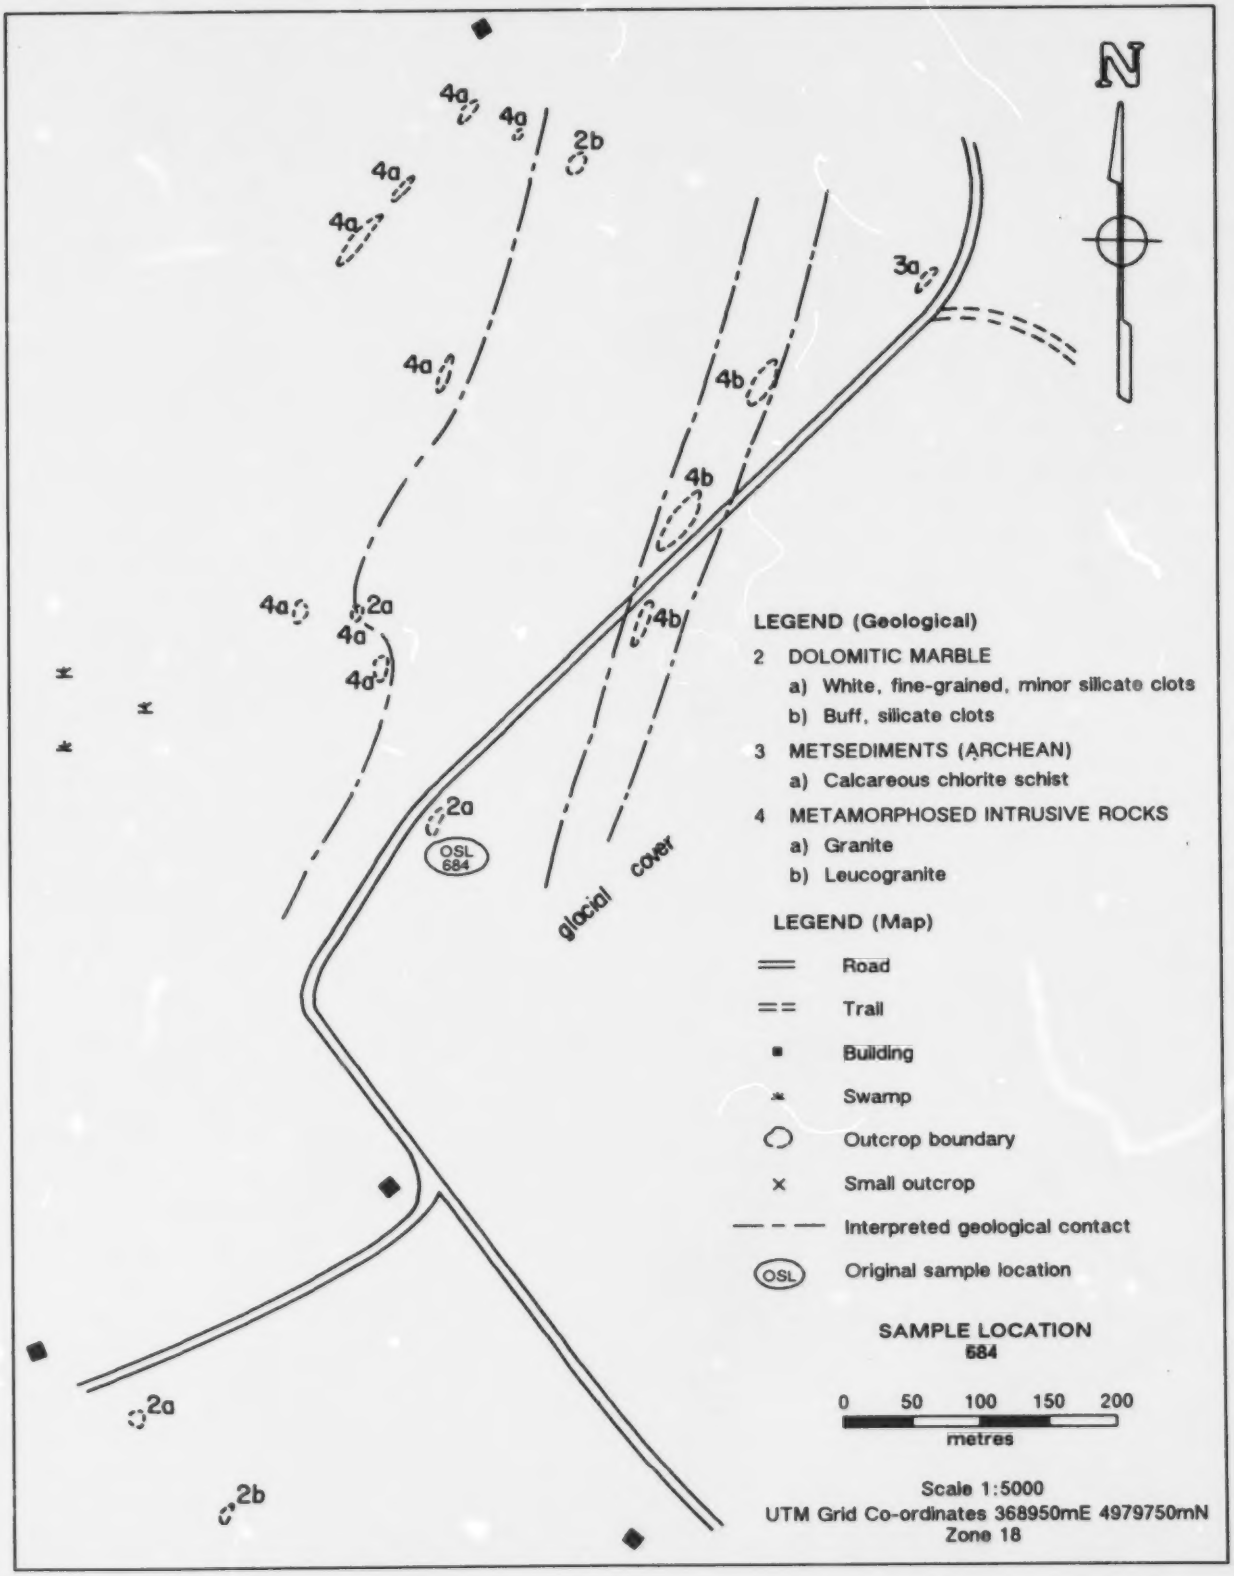

Figure 95. *Location Map, Sample 684.*

MAP AREA 708/709

Location

Southeast corner of Palmerston Township.

Map reference: NTS 31C/15.

708—UTM 366400mE, 4973600mN, Zone 18.

709—UTM 366300mE, 4973300mN, Zone 18.

Access

Approximately 3 km north of Clarendon Station on a north-trending road, Concession VIII, Lot 4.

Regional Geology

This map area includes part of a narrow marble belt which trends northeast from Mississippi Station to Gordon Rapids. This belt is bounded by mafic intrusive rocks to the west and by granitic intrusive rocks to the east. This marble belt forms a zone of intense shearing between dioritic and granitic intrusive rocks (Smith 1958).

Local Geology

The detailed map area (Figure 96) is underlain by dolomitic marble of varying impurity content, and by hornblende amphibolite which is in sharp contact with the marble. Impurities within the dolomitic marble occur as silicate clots and bands, often in excess of 50 percent. Calcitic marble contains minor amounts of tremolite along with silicate clots. Hornblende amphibolite occurs in the southwest section of the map in contact with the marble, and also as a discontinuous lens within the marble.

Previous Geological Work

Palmerston Township has been mapped by Smith (1958), Hewitt (1964a), and Pauk (1982, 1987).

Chemistry

The majority of samples taken from within the marble belt (samples 687, 688, 708, and 709) are dolomitic in composition. These samples have low impurity contents with SiO_2 less than 1 weight percent. Trace and metallic element contents are low throughout this belt.

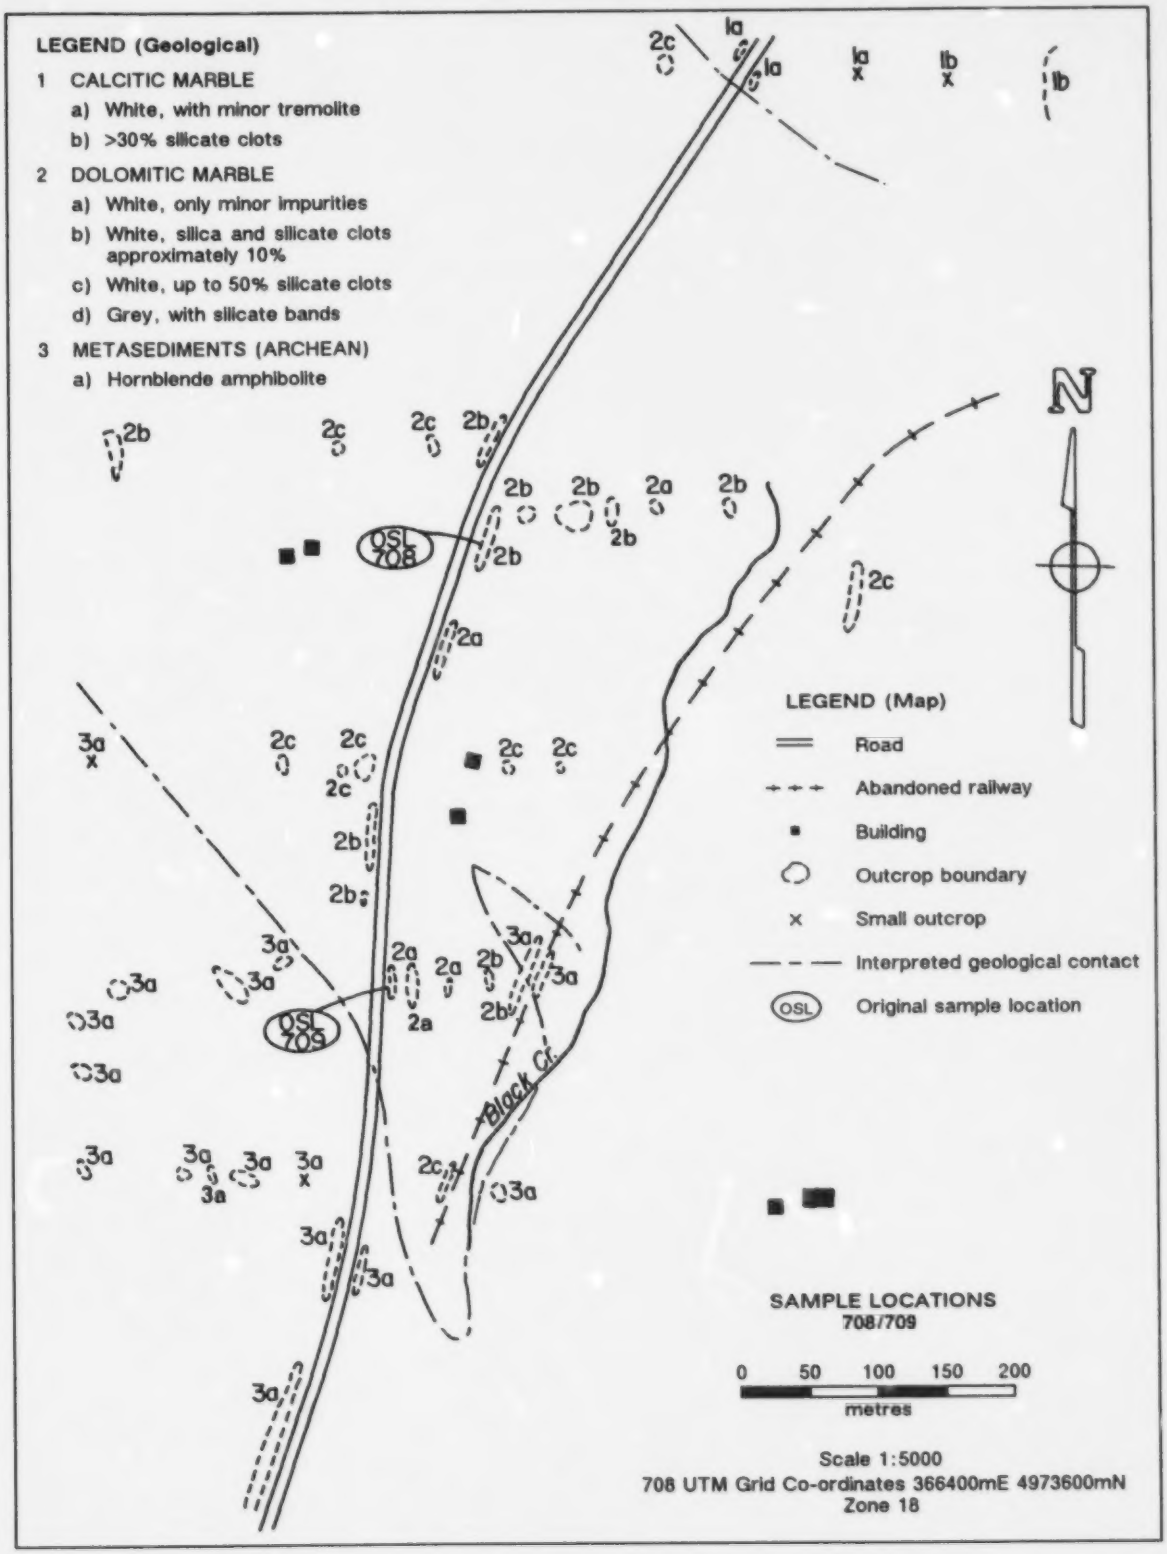

Figure 96. *Location Map, Samples 708 and 709.*

MAP AREA 835

Location

Northeast corner of Faraday Township.

Map reference: NTS 31F/4; UTM 264400mE, 4988900mN, Zone 18.

Access

2 km north of Highway 28, 300 m east of Monck Road, Concession B, Lot 28.

Regional Geology

Nearly half of Faraday Township is underlain by marble of differing compositions. The marble is interbedded with metasediments and intrusive rocks of mafic and granitic composition. The belt from which this sample was taken is slightly north of a larger marble belt. It is separated from the larger belt by a band of metasediments.

Local Geology

Detailed mapping of the area (Figure 97) reveals that the area is underlain by massive white marble of calcitic and dolomitic composition. The least contaminated marbles of calcitic and dolomitic composition contain minor amounts of phlogopite and pyrite. Impure marble contains clots and bands of silicate and calc-silicate material. Small pegmatitic bodies occur within the marble without any visible alteration around them.

Previous Geological Work

Faraday Township has been mapped by Adams and Barlow (1910), Hewitt and Satterly (1957), and Hewitt (1959).

Chemistry

Most of the samples from this belt (samples 833 to 843) have low SiO_2 contents with either calcitic or dolomitic compositions. Trace and metallic element contents are low throughout the entire area.

Appendix A

Analytical Results

This appendix includes the analytical results of 1912 marble samples collected in Southeastern Ontario. The locations of these samples are plotted on Chart A (back pocket).

Sample numbers 31x through 1912z are channel samples taken from the detailed map areas (Figures 28 through 97). Sample locations are plotted on the relevant detailed map area figures. Channel samples were taken perpendicular to the strike over 1 to 2 m distances.

Appendix B

Elemental Statistics

Statistical values for 19 elements and also Loss on Ignition (LOI) are presented for Part 1 data set (1778 samples). These statistics are categorized according to the CaO/MgO ratio and SiO_2 content as discussed under the section on "Ternary Diagrams".

Statistical values for Part 2 data set may be examined at the Office of the Resident Geologist, Southern Region, Tweed.

Element CaO

Classification	Number of Observations	Mean (%)	Std. Dev. (%)	max. (%)	min. (%)	95%ile	98%ile
1. pure calcite	87	57.22	2.74	61.36	39.10	60.91	61.56
2. pure dolo-calcite	450	51.77	2.97	59.60	43.00	56.05	57 47
3. pure calc-dolomite	52	36.58	4.00	43.10	30.86	43.35	43.74
4. pure dolomite	151	29.67	0.60	31.30	25.30	30.66	30.83

Appendix C

Sample Descriptions

Descriptions of outcrop geology were taken for each of the samples in order that correlations might be made with analytical results. These descriptions are on file at the Office of the Resident Geologist, Southern Region, Tweed. Brief summaries of the sample descriptions are given using appropriate symbols for the different sample characteristics and impurities.

TABLE C.1. CARBONATE SAMPLING PROGRAM SAMPLE DESCRIPTIONS LEGEND.

Colour

w	–	white	or	–	orange
g	–	grey	bf	–	buff
lg	–	light grey	lbf	–	light buff
dg	–	dark grey	y	–	yellow
mg	–	medium grey	br	–	brown
pk	–	pink	bk	–	black
bl	–	blue			

Grain Size

f	–	fine (<1 mm)
m	–	medium (2 to 4 mm)
c	–	coarse (>5 mm)

Impurities

bio	–	biotite	mag	–	magnetite
phlog	–	phlogopite	serp	–	serpentine
mus	–	muscovite	fel	–	feldspar
q	–	quartz	act	–	actinolite
gf	–	graphite	aug	–	augite
sp	–	sphalerite	talc	–	talc
hem	–	hematite	chl	–	chlorite
clots	–	clots	tour	–	tourmaline
hb	–	hornblende	lim	–	limonite
py	–	pyrite	diop	–	diopside
c-s	–	calc-silicates	gt	–	garnet
trem	–	tremolite	cp	–	chalcopyrite

Structure

mas	–	massive
lam	–	laminated
fol	–	foliated

Sample No.	Colour	Grain Size	Impurities	Structure
1	br	–	q,hem,hb,phlog	lam
